1 Executive Summary

Air pollutants emitted from Department of Defense (DoD) facilities can interfere with military activities or in some cases even threaten life and property. These emissions can contribute to local concerns on the military base and neighboring communities, and regional air quality problems can occur through long-range transport and transformation processes. In some cases, operations performed for the benefit of one component of the ecosystem may have adverse effects. For example, prescribed burnings performed on a base primarily to save the habitat of an endangered species may have contributed to the air quality problem in a nearby metropolitan area. Faced with such complex problems, DoD needs reliable tools to determine the impact of its operations on the environment. In particular, air quality simulation models are needed that can help determine the impacts of various types of emissions from military installations on air quality. Existing air quality models have limited reliability to respond to such needs.

The objective of this project was to enhance current air quality models in order to simulate the air quality impacts of military activities. Two techniques developed earlier, adaptive grid modeling and direct sensitivity analysis, have the potential to improve the ability of the models to capture source-receptor relationships between emissions at local scales and air quality at the regional scale. While adaptive grid modeling can fill the gaps between local and regional scales, the direct sensitivity analysis allows the impacts of specific sources to be discerned from cumulative effects on regional air quality.

In this study, a new air quality model that incorporates the adaptive grid and sensitivity analysis techniques was developed. A code review was conducted and test simulations were performed to verify that the new model fulfills the design requirements. August 15-18, 2000 period was simulated to determine the air quality impacts of the prescribed burning operation at Fort Benning, Georgia. The impact on Columbus metropolitan area is of particular interest. Ozone levels as well as their sensitivity to nitrogen oxide (NOx) and volatile organic compound (VOC) emissions from the fires were modeled. Emission rates from the burns were estimated from the fire data which include the location, time and acreage of the burns, using the First Order Fire Effects Model (FOFEM). Data for other emissions in the region were obtained from an ongoing air quality study. Several simulations were performed with the air quality model that is equipped with the new techniques as well as the base model. The adaptive grid in the new model enabled better resolution of the plumes caused by prescribed burns. The sensitivity of ozone concentrations to the fires was also better resolved in comparison to the brute-force method which takes the difference between two old-model simulations: one without and another with the fires. The adaptive model with direct sensitivity captured the near-source reduction and downwind increase in ozone concentrations due to the fires. This non-linear response of ozone, which is also observed in power plant plumes, was totally missed by the base model. In view of these results, it was concluded that the new model, enhanced by adaptive grid and sensitivity analysis techniques, can be used for accurate assessment of the air quality impacts of most DoD activities.

The results from this effort are expected to directly benefit the management of prescribed burning at Fort Benning. Additionally, the techniques developed can be used for the general purpose of predicting the fate of air pollutant emissions from aviation, ship, or coastal operations. Products can be developed to assist site managers in responding to immediate needs as well as in planning future emissions that will minimize the negative impacts on local and regional air quality. This project was completed in FY 2002.
2 Introduction

This project is about the fate of air pollutants associated with the Department of Defense (DoD) activities. Emissions from military installations may directly interfere with military activities such as training exercises, or in some cases even threaten life and property. They may jeopardize wildlife on the base and pose a risk to the neighboring communities. Further, through long-range transport and transformation processes, these emissions may contribute to regional air-quality problems. In some cases, operations performed for the benefit of one component of the ecosystem may have adverse effects on another component. For example, as will be described below, prescribed burnings performed on a base primarily to save the habitat of an endangered species may have contributed to the air quality problem in a nearby metropolitan area. Faced with such complex problems, DoD needs reliable tools to determine the impact of its operations on the environment. In particular, air quality simulation models are needed that can help determine the air quality impacts of emissions from military installations.

At their current state, existing air quality models would fall short of responding to DoD needs such as those described above. Our objective is to improve the ability to predict the impacts of air pollutants emitted as a result of military operations on the surrounding environment. The atmospheric and chemical modeling systems currently used by various agencies tend to focus on a single scale that seems to be the most relevant to a particular air pollution problem (e.g., global climate models or local scale accidental release models). However, the study of the impact of DoD facilities requires the investigation of the interaction between various scales due to the fact that both the location of the facilities and the lifetimes of emitted pollutants are conducive to long-range transport. Existing modeling systems need improvement in their representation of source-receptor relationships over a wide range of scales in order to predict accurately the ultimate fate of pollutants emitted from specific sources such as DoD facilities.

Recently, we have developed two unique techniques that would improve current air quality models by filling the gaps between the scales from local to regional and by discerning the impacts of specific sources from cumulative effects on regional air quality. These techniques are: 1) Adaptive grid modeling, and 2) Direct sensitivity analysis. We have developed both of these techniques to a level where they have been successfully applied to very relevant air quality problems. However, for application to DoD-related systems, a proof-of-concept was necessary to show that the techniques would work under the unique conditions of DoD operations. Although the techniques were developed with similar applications in mind, the primary objective has not been, for example, source apportionment at the facility level. This project aims to provide an early assessment of potential benefits.

To achieve the objectives stated above, we tested the two techniques within an advanced air quality model, in an urban-to-local scale application, to determine the impact of the prescribed burning operation on the ozone levels in a downwind metropolitan area. We assessed the potential of these new techniques in bringing the models to the desired level of reliability. This application is particularly important since the metropolitan area was recently declared a non-attainment area, and intends to get back in compliance with the national air quality standards as quickly as possible. There are several other sources affecting the ozone levels and it is critical to determine the incremental contribution of the DoD operation to develop a strategy for attainment.

In this project, the particular focus was on prescribed burning emissions from a military reservation at Fort Benning, Georgia, and their impact on local and regional air quality. However, the techniques are general enough for application to other military operations. We could target
other types of emissions, for example from aviation, ship, or coastal operations at various locations, in this project. Once the concept is proven, the techniques can be used for the general purpose of predicting the fate of air pollutant emissions from various military sources. Products can be developed that can assist site managers in responding to immediate needs, as well as being able to plan future emissions that will minimize the impact on the environment. This would be particularly advantageous in regions where such facilities must meet local pollution standards and where ambient concentrations of some pollutants are already high due to contributions from other anthropogenic and/or natural sources.

3 Problem Statement

3.1 Prescribed Burnings at Fort Benning

The reasons for prescribed burning at Fort Benning include to improve and maintain endangered species habitat, reduce hazardous fuels, prepare sites for seeding and planting, manage understory hardwoods, control disease, improve forage for grazing, enhance appearance, and improve access. The objective is to convert the landscape as close to its pre-settlement condition (a pine overstory with grasses, legumes, and other herbaceous vegetation as a ground cover) as possible. In 1994, Fort Benning received a Biological Opinion from the Fish and Wildlife Service stating that the actions on the base were likely to jeopardize the endangered red-cockaded woodpecker (RCW) habitat. One of the most economical means of maintaining the longleaf pine habitats is prescribed burning. Approximately 30,000 acres must be prescribed burned each year, during the growing season (March through August). This period falls within the “ozone season.” In order to restore the RCW habitat, longleaf seedlings are planted. Prescribed burnings continue from August through October for site preparation purposes which also overlaps with the ozone season. These fires reduce unwanted vegetation that would compete with longleaf seedlings.

Prescribed burning is an efficient and effective means to reduce fire fuel build-up. Heavy roughs can build up posing a serious threat from wildfire to lives, property, and all natural resources. A burning rotation of approximately 3 years is usually adequate to fire proof pine stands and reduce this threat. Prescribed burning helps control undesirable species which compete with pines. It also controls brownspot disease, which is a fungal infection that weakens and eventually kills longleaf seedlings. Burning increases the yield and quality of herbage, legumes, and browse from hardwood sprouts. Wildlife species such as deer, turkey, quail, and doves also benefit from prescribed burning. Prescribed burning on a regular basis also serves a military need by providing a safer training environment with improved access and visibility. Lastly, growing season burns have significantly reduced the tick population on the installation.

Operational and safety constraints limit the burnings to an average of 300 acres per day (Environmental Management Division, 2000). For example, although an attempt is made to burn all RCW clusters during the growing season it is logistically impossible due to the number of clusters (75-80 annually) and scheduling conflicts with training. Currently, ignition is accomplished with hand crews and drip torches. While this provides better control with respect to where the fire is applied and when, it is difficult to control the intensity of the fire. Natural firebreaks such as roads, trails, drains, and creeks dictate the size of burn areas. All these limitations make it necessary to continue the burnings throughout the year. In realization of the Columbus ozone problem, the majority of the burnings (70-75%) were shifted to the January-April period, which is outside the “ozone season.”
Currently, the only external constraint on prescribed burning arises as a result of smoke management concerns. Smoke complaints and the threat of litigation from smoke-related incidents/accidents are the primary concerns. Fort Benning follows voluntary (not mandated by state or federal government) smoke management guidelines in an effort to minimize the adverse impacts from smoke. An additional concern is the effect of prescribed burning on ozone levels in Columbus. Forest fires produce nitrogen oxide and hydrocarbon emissions that form ozone (Cheng et al., 1998; Battye and Battye, 2002; Ottmar, 2001). These pollutants may be transported downwind, mix with emissions from other sources and contribute to the poor air quality in urban areas. Sulfur dioxide and particulate matter emissions from forest fires are also of concern but, in general, they do not have a direct influence on the urban ozone problem. The ozone alert season is from 1 May through 30 September in Georgia. It is during this season that emissions from prescribed burning operations could affect smog levels in Columbus. In collaboration with the Partnership for a Smog-Free Georgia (PSG), Fort Benning is avoiding prescribed burns when meteorological conditions are conducive to ozone buildup. If Columbus shows a trend toward more days with elevated ozone levels, it will become more critical to design burning strategies that can adapt to changing weather parameters.

### 3.2 Limitations of Current Air Quality Models

The atmospheric and chemical modeling systems currently used by various agencies tend to focus on a single scale that seems to be the most relevant to a particular air pollution problem. Global scale models address climate issues while regional scale models are used for the tropospheric ozone, regional haze or acid deposition studies. Urban scale smog models are being replaced with urban-to-regional scale models in most places where transport from other upwind sources play an important role. On the local scale, models are used to deal with problems such as accidental releases. The domains of local scale models are limited by design; therefore, they cannot be used for regional scale impact studies.

One of the most advanced urban-to-regional scale models is the Multiscale Air Quality Simulation Platform (MAQSIP) (Odman and Ingram, 1996). Urban-to-regional scale models are used in developing emission control strategies for problems such as urban and regional ozone, acid deposition, or regional haze which is attributed to primary (emitted) and secondary (formed in the atmosphere) fine particulate matter. While these models are equipped with special tools to treat emissions from large power plants (Karamchandani et al., 2000), they lack the ability to resolve emissions from relatively small area sources such as those from prescribed burnings. To account for such area sources, the models rely on grid resolution. Prescribed burnings are performed over areas as small as one square kilometer (approximately 200 acres). This scale is too small for typical regional applications. Therefore, emissions from prescribed fires are blended with emissions from many other sources within the same grid cell of regional scale models. This would make it impossible to conduct an impact study that would target emissions from biomass burnings.

Another limitation of current air quality models is related to numerical errors involved during the simulations. Let us suppose that the grid cell size could be reduced to one square kilometer by using nested-grid techniques (Odman et al., 1997). In that case, a typical prescribed burning unit would cover a single grid cell. The effect of having or not having prescribed burning emissions from a single grid cell would be a small perturbation for air quality models. As the perturbation gets smaller in size, numerical errors that affect the simulation results become more important. The results of an impact study such as the one here would be highly uncertain if the models were used as is. Therefore, urban-to-regional scale models, in their current state, are not very reliable tools for determining the impact of prescribed burning emissions to the surrounding environment.
The study of the impact of biomass burning from DoD facilities requires investigation of the interaction between various scales due to the fact that both the location of the facilities and the lifetimes of emitted pollutants are conducive to long-range transport. Below, we describe a methodology to improve current urban-to-regional scale air quality models with two modeling techniques. These techniques improve representation of the transport and transformation processes over a wide range of scales and provide more reliable source-receptor relationships. The product is a more reliable tool that can predict accurately the ultimate fate of pollutants emitted from specific sources such as DoD facilities.

4 Methodology

Recently, we have developed two unique techniques that can improve the air quality models by filling the gaps between the scales from local to regional and by discerning the impacts of specific sources from cumulative effects on regional air quality. They are: 1) Adaptive grid modeling, and 2) Direct sensitivity analysis. These techniques improve representation of the transport and transformation processes over a wide range of scales and provide more reliable source-receptor relationships. An air quality model equipped with these two techniques would be a more reliable tool that can predict accurately the ultimate fate of pollutants emitted from specific sources such as DoD facilities. In this section we describe the two techniques in detail and overview the air quality modeling platform.

4.1 Adaptive Grid Modeling

We developed an adaptive grid modeling approach to reduce the uncertainty in air quality predictions. By clustering the grid nodes in regions that would potentially have large errors in pollutant concentrations, the model is expected to generate much more accurate results than the traditional fixed, uniform grid counterparts. The repositioning of grid nodes is performed automatically through the use of a weight function that assumes large values when the curvature (change of slope) of the pollutant fields is large. The nodes are clustered around regions where the weight function bears large values, thereby increasing the resolution where the error is large. Since the number of nodes is fixed, refinement of grid scales in regions of interest is accompanied by coarsening in other regions where the weight function has smaller values. This yields a continuous multiscale grid where the scales change gradually. Unlike nested grids, there are no grid interfaces, which may introduce numerous difficulties due to the discontinuity of grid scales. The availability of computational resources determines the number of grid nodes that can be afforded in any model application. By clustering grid nodes automatically in regions of interest, the adaptive grid technique uses computational resources in an optimal fashion throughout the simulation.

A detailed description of the technique can be found in Srivastava et al. (2000). Here we will not repeat that information; instead, we will try to illustrate the technique and its potential with relevant applications. The adaptive technique was applied to problems with increasing complexity and relevance to air quality modeling. First, it was applied to pure advection tests (Srivastava et al., 2000). In a rotating cone test, the adaptive grid solution was more accurate than the fixed uniform grid with the same number of grid nodes. The error in maintaining the peak of the cone was only 13% compared to 39% with the fixed grid: an accuracy that could only be achieved by using 22 times more grid nodes with a fixed uniform grid. In a second test, four cones were rotated to measure the performance of the algorithm in following multiple features. Once again, the peak accuracy was better than the fixed uniform grid alternative. The peak error increased to 23% since the grid nodes, whose number was the same as in the previous test, were being...
clustered around four cones instead of one. Srivastava *et al.* (2001a) conducted a third test with concentric conical puffs of NO, and VOCs reacting in a rotational wind field. The parameters of this problem are such that, after a certain time, ozone levels drop below the background near the base of the conical puffs but they peak near the vertex of the cones. This feature was resolved by the adaptive grid solution while it was completely missed by the uniform fixed grid solution. When nine times more grid nodes were used, the fixed grid was finally able to reveal this feature but not as accurately as the adaptive grid technique. The overhead involved in adaptive grid computations is much smaller than the time spent in computing the chemical kinetics for these additional nodes. Overall, the adaptive grid algorithm is about 10 times more efficient than the uniform grid alternative for the same level of accuracy.

Next, the adaptive grid technique was applied to the simulation of a power plant plume (Srivastava *et al.*, 2001b). A two dimensional plume with a VOC/NO, emission ratio of 14% was advected with uniform winds and diffused over a background with a VOC/NO, ratio of 35. Other parameters were chosen to make the dispersion as realistic as possible. After about 12 hours of simulation, the composition of the plume was analyzed taking cross sections at various downwind distances. At 10 km downwind, the adaptive grid solution showed a NO, rich, but ozone deficient core. This feature, which is also observed in actual power plant plumes, was completely missing in the uniform grid solution, which artificially diffused the NO, and displayed highest ozone levels at the core of the plume. The adaptive grid, on the other hand, had ozone bulges developing near the plume edges. At a downwind distance of 30 km, these bulges continued to grow as NO, diffused slowly from the core to the edges (at a rate more in line with physical diffusion) and radicals were entrained into the plume. This plume structure started disappearing after about 80 km. At a downwind distance of 135 km, the plume was fully matured with an ozone peak at the center. The peak ozone concentration was larger than one predicted by the fixed uniform grid. A similar evolution of the plume was observed in the fixed uniform grid solution when the number of grid nodes was increased by a factor of nine. However, this solution was about five times more expensive than the adaptive grid solution.

Another relevant application was the multiple source test, where an imaginary city was placed at the center of a domain with diagonal winds (Odman *et al.*, 2000b). The city consists of an inner circular source representing urban conditions and an outer circle representing suburban conditions. The VOC/NO, emission ratios are 5 and 9, respectively. There are two identical point sources with a VOC/NO, emission ratio of 14%: one is located upwind and the other downwind from the city. The background has a VOC/NO, ratio of 10. Figure 2 of Section 5.b shows the adaptive grid at the beginning of the simulation and 12 hours later. The locations of the sources are clearly visible in the initial grid. Note that the grid nodes are clustered around the point sources and at the transitions from the background to the outer suburban circle and from the suburban to the urban circles. Once the simulation started, the nodes continued to cluster around the upwind source but moved away from the downwind source towards the upwind end of the city. This behavior was mostly due to a more uniform ozone field downwind of the city.

After these and other testing of the algorithm (Odman *et al.*, 2001; Khan *et al.*, 2003), finally an adaptive grid AQM was developed (Odman *et al.*, 2002). The model was applied to an ozone simulation in the Tennessee Valley (Khan and Odman 2003). Ozone results from this application were evaluated and showed significant improvement over those from fixed grid models, even those employing up to four times more grid cells. In several cases the agreement with observations was better compared to fixed grid models. When the reasons were investigated it was found that the complex source-receptor relationships, especially the long-range ones were much better resolved with the adaptive grid.
4.2 Direct Sensitivity Analysis

Sensitivity analysis is essential in determining source-receptor relationships and designing emission control strategies. The traditional “brute-force” method involves running the model several times, each time perturbing one type of emission (e.g., NO, or VOC) from a different source. If the perturbation is small, the brute-force method may not yield accurate sensitivities due to numerical errors propagating in the model. Our group has developed a new and powerful direct sensitivity analysis technique to study the response of air quality to various types of emissions (Yang et al., 1997). Unlike the brute force approach, this technique is not limited by the magnitude of the perturbation and, in theory, it can be used for even infinitesimal changes in emissions. Therefore, the technique has the potential of improving current models to a level where they can be used for impact analysis of relatively small sources such as military installations.

Air quality models are based on the atmospheric diffusion equation:

\[ \frac{\partial c_i}{\partial t} + \nabla \cdot (u \, c_i) = \nabla \cdot (K \nabla c_i) + R_i + S_i. \]  

(1)

Here, \( c_i \) is the concentration of the \( i \)th pollutant species, \( u \) describes the velocity field, \( K \) is the diffusivity tensor, \( R_i(c_1, c_2, ...) \) is the chemical reaction term and \( S_i \) is a source term for certain types of emissions. The local sensitivity of the concentration of a species (e.g., ozone) to a certain emission type (e.g., NO, or VOC) from a particular source can be defined as:

\[ s_{ij}(t) = \frac{\partial c_i(t)}{\partial E_j}. \]  

(2)

Here, \( s_{ij} \) is the sensitivity of \( c_i \) to emission \( E_j \). Using direct derivatives of Equation (1) the following equation can be obtained for sensitivities.

\[ \frac{\partial s_{ij}^*}{\partial t} = -\nabla(u s_{ij}^*) + \nabla(K \nabla s_{ij}^*) + J_{ik} s_{kj}^* + \frac{\partial R_i}{\partial E_j} + \frac{\partial S_i}{\partial E_j} - \nabla(u c_i) \delta_{ij} + \nabla(K \nabla c_i) \delta_{ij}. \]  

(3)

Here, \( s_{ij}^* \) is the semi-normalized sensitivity coefficient, \( J_{ik} \) is the Jacobian matrix, \( c_i \) is a scaling variable with a nominal value of 1, and \( \delta_{ij} \) is a binary variable (either 1 or 0). Since the sensitivities to different emissions can vary by many orders of magnitude, it was necessary to define semi-normalized sensitivity coefficients, \( s_{ij}^* \).

The similarities between Equations (1) and (3) allow us to use the same or very similar numerical solution techniques and calculate local sensitivities to emission sources simultaneously along with the species concentrations. This also makes the implementation of the technique in any model relatively straightforward. The technique is also computationally efficient because several of these sensitivities (the number being limited by available core memory) can be calculated simultaneously with a fractional increase in CPU time. The emission sources can be discerned by type as point, area, mobile, or biogenic, and by composition such as \( \text{SO}_2 \), \( \text{NO}_x \), or VOC. Also, the location of the emission source can be specified, for example, as the boundaries of a DoD facility (to the grid scale resolution). The technique would predict the sensitivity of air
quality at any desired location in the modeling domain (e.g., sensitivity of ozone concentrations at a downwind urban center) to a fractional change in the emissions from the source of interest.

The technique has been evaluated in an application to the Southern California where the sensitivities of ozone concentrations to the domain wide reductions of mobile and area sources of NO, were compared to a brute-force method (Yang et al., 1997). This technique was used in an integrated modeling system focusing, simultaneously, on ozone, particulate matter and acid deposition (Boylan, et al., 2001). We investigated the sensitivity of particulate matter concentrations to the reductions of SO₂ and NOₓ emissions in the Southern Appalachian Mountains region. We also investigated the sensitivity of ozone concentrations to NOₓ and VOC emissions from different states, using state boundaries as sub-regions. As part of that project, we compared our method to the brute-force approach for ozone sensitivities to domain wide NOₓ and VOC emissions. The general agreement between the direct sensitivity and the brute-force method shows that the former is a reliable tool. Whenever we observed differences, we were able to relate the difference to the numerical errors associated with the brute force technique and show that the direct sensitivity method yields results that are more accurate.

Note that in all of the applications thus far, we have focused on a relatively large perturbation such as a reduction over the entire domain or an entire state in a region as big as the Eastern U.S. When the focus is shifted to a small contributor, such as a single DoD facility in a large region, the results of a brute-force analysis would be very unreliable. This is more so if the facility is surrounded by other sources of emissions of the same type. As mentioned several times before, the reason is that the perturbation may be below the numerical detection limit of the model. It is very likely that numerical errors in the model would be larger than the perturbation so that a noise is obtained, instead of an accurate response, from the brute-force analysis. The direct sensitivity analysis on the other hand is not subject to such a limitation and even the response of an infinitesimal change in emissions can be detected accurately.

4.3 Air Quality Modeling

The platform of choice for the incorporation of the adaptive grid modeling and direct sensitivity analysis techniques is the Multiscale Air Quality Simulation Platform (MAQSIP) (Odman and Ingram, 1996), which is an early prototype of the Community Multiscale Air Quality (CMAQ) (Byun and Ching, 1999). MAQSIP is a state-of-the-art pollutant transport and chemistry model. The following attributes of MAQSIP distinguish it from other models.

1) Modular: MAQSIP is a truly modular platform where physical/chemical processes are cast into modules following the time-splitting approach. Each process module operates on a common concentration field. Other variables are encapsulated within each module.

2) Flexible: MAQSIP has alternative modules for various processes.

3) Expandable: New modules can be (and are being) added to the platform by scientists using MAQSIP in their research.

4) Multiscale: MAQSIP supports multiple, multi-level nested grids.

5) Generalized Coordinates: MAQSIP can support practically any coordinate system.
The MAQSIP model offers the user a choice among the CB-4 and SAPRC-99 chemical mechanisms. For the type of emissions involved in prescribed burning, both mechanisms offer similar ozone formation pathways. In an application to California, CB-4 and SAPRC-99 mechanisms gave essentially the same results for ozone, and while the SAPRC mechanism offers more detail, the CB-4 mechanism is computationally faster. Investigating the effect of different chemical mechanisms on the results is beyond the scope of this project and since their ozone pathways are very similar either mechanism could be used. For this study CB-4 mechanism was selected.

The adaptive grid version of MAQSIP is described in detail elsewhere (Odman et al., 2001 and 2002). The grid adaptation was restricted to the horizontal plane and the same grid structure was used for all vertical layers. Air quality models such as MAQSIP have unequally spaced vertical layers designed to better resolve mixing in the Planetary Boundary Layer. Typically, starting from about 20 m at the surface, layer thickness increases as the model is extending to the upper troposphere. Adaptation in the horizontal plane has no direct effect on this vertical resolution.

A weight function determines where grid nodes must be clustered to obtain a more accurate solution. In this study, the curvature in the concentrations of an inert fire tracer was used to calculate the weight function that drives the adaptation. The tracer is assumed to be a product of the fires at Fort Benning emitted at the same rate as the NO emissions from the fire. The tracer is transported and deposited in the same way as other fire species but it is non reactive.

The presence of convective clouds is an important factor that affects pollutant levels. Cloud scavenging of gaseous pollutants and aerosol formation in clouds are important processes that must be characterized in air quality models. However, for the ozone episode that was investigated in this proof-of-concept study, clouds and precipitation were not major factors. The scenario simulated had clear sky conditions conducive to photochemical ozone formation. A follow on project, which addresses secondary PM formation, can thoroughly investigate the processes related to clouds and precipitation. In addition, in relation to the adaptive grid modeling, the presence of clouds presents a good reason for developing three-dimensional adaptation techniques.

5 Accomplishments

5.1 Data Preparation

The episode selection is based primarily on the availability and quality of meteorological and emissions data as well as the impact potential of prescribed burns at Fort Benning on regional air quality. As part of Fall Line Air Quality Study (FAQS), we have already simulated several episodes during summer of 1999 and 2000 in Georgia using MM5 meteorological model and SMOKE emissions model. The ideal scenario for our case study is one with southeasterly winds, biomass burning performed at Fort Benning and high ozone levels observed at Columbus. The Host Site Coordinator of the SERDP Ecosystem Management Project (SEMP) at Fort Benning, Mr. Hugh Westbury, was very instrumental in providing the fire data for the years 2000-2001. Based upon meteorological conditions and fire data a four-day period, August 15-18 2000, was selected for modeling. Fires were reported at Fort Benning on those days and there are periods during which the winds were southeasterly hence it is possible that fires may have affected air quality in Columbus. Table 1 shows the data for the fire events on those days.
Data preparation efforts included meteorological and emissions data preparation as well as post-processing. Meteorological data were obtained from FAQS. Detailed information on meteorological data preparation is given elsewhere (Hu et al., 2003a). Similarly, emissions data were obtained from FAQS study. More information on emissions data can be obtained elsewhere (Unal et al., 2003; Hu et al., 2003b). For biomass burning emissions, First Order Fire Effects Model (FOFEM) Version 5, developed by Intermountain Fire Sciences Laboratory was utilized. In this model, fuel type was assumed as natural fuel with long leaf pine trees. For some of the pollutants, such as speciated VOCs and NOx, emission factors provided by Battye and Battye (2002) were utilized. Table 2 shows the estimated emissions for biomass burning.

5.2 Model Preparation

The task here was to install the direct sensitivity analysis technique, which we have previously developed for a static grid model, into the adaptive grid version of MAQSIP. This required several modifications to the algorithm and the computer code. The most important change is the treatment of the emission source during the calculation of sensitivity to that source. Since an emission source is fixed with respect to the static grid, in the old code the grid cells overlapping the emission source (e.g., location of the fire) were being flagged before the simulation. Then, the sensitivity of the emitted species in the flagged cells was being set equal to the emission rate into that cell. In the adaptive grid model, since the grid nodes are constantly moving, the grid cells cannot be flagged beforehand. Also, the intersection of the emission source with each cell keeps changing. An algorithm was devised to find this intersection. In the new code, the sensitivity of the emitted species in each cell is being set equal to the emissions per unit area times the intersection area of the cell with the emission source. Another change worth noting is the addition of an inert fire tracer species to drive the grid adaptation. This tracer is transported just like the other species and the grid is adapted to the curvature in the tracer’s concentration.

In order to verify the new model which incorporates the adaptive grid and sensitivity analysis techniques, a test simulation was performed with fire emissions under controlled meteorological conditions (i.e., constant winds). The sensitivity results obtained with the new model have been compared to the “brute-force” sensitivity (i.e., the difference between two runs: one with and another without the fire emissions) obtained from the old model (i.e., static grid MAQSIP). Initially, the sensitivities from the two models were significantly different so the new model could not be verified. A quick review of the critical modules revealed several programming mistakes or “bugs.” To identify the few remaining "bugs", the computer program was reviewed by the principal investigator and a programmer. In this review, the flow of the program was followed through a debugger during a typical simulation. After the remaining bugs were found and fixed, it was concluded that the program properly executed the operations described in the algorithm. In addition, the results of test simulations showed that the computer program fulfills the requirements of the original design. Therefore, the new model was declared “verified” and ready for simulations.

5.3 Simulations

Emissions and meteorology data were processed to prepare the inputs required to run the air quality model. Simulations were conducted in three stages:
(1) Simulation of the selected episode with 4x4 km² static grid version of the MAQSIP model;
(2) Simulation of the selected episode with the new version of the MAQSIP model incorporating the adaptive grid and direct sensitivity analysis techniques.

Static Grid Simulations

To be used for comparison in the evaluation of the new model, the selected episode was simulated with a 4x4 km² static grid version of the MAQSIP model. Lambert Conformal projection with parameters of 30°N, 60°N, and 90°W, centered at 40°N and 90°W, was utilized for the domain. The 4x4 km² grid has 102 columns and 78 rows with 13 vertical layers. The results of the static grid run were compared with outputs from CMAQ model for the same location and time.
period generated during the FAQS project. The comparison showed that static grid results were similar to the CMAQ results. Since CMAQ results were already compared with observed air quality data and found to be an accurate representation of actual conditions, no further evaluation of the static grid MAQSIP results (i.e., with observations) was performed. A second run was also made including emissions from the fires at Fort Benning. The difference between the concentrations of these two simulations yields the static grid “brute-force” sensitivities.

**Adaptive Grid Simulations**

The adaptive grid also used the same domain definitions as for the static grid. In adaptive runs the concentration of an inert fire tracer was used to calculate the weight function that drives the adaptation. The tracer is assumed to be a product of the fires at Fort Benning emitted at the same rate as the NO from the fires. The tracer is transported and deposited in the same way as the other fire species but it is non reactive. Two different runs were made with the adaptive grid model. These runs include: one run with base emissions; and one run with base emissions plus fire emissions, which also has the direct sensitivity calculations. In both runs the grid adapted to the same fire tracer, therefore the grids are identical in both simulations. The difference between the concentrations of these two simulations yields the adaptive grid “brute-force” sensitivities. Direct sensitivity results were compared with “brute-force” and it was observed that differences were within the bounds of previously reported differences (Hakami et al., 2003). Only direct sensitivities will be used hereafter.

**Simulation Results**

First we compared the adaptive grid model with the static grid model. The tracer concentrations calculated by the two models as a result of fires at Fort Benning on August 15, 2000 at 19:00 Greenwich Mean Time (GMT) are shown in Figures 1 and 2. During this period two different fires happened at two different locations. The fire to the south is emitting at a higher rate than the northern one since the area burnt is almost 1.5 times bigger. The location of these fires can be seen in both static and adaptive simulation results.

One of the significant differences between these simulations is the fact that static grid distributes emissions uniformly to the 4x4 km² cell area where the fire takes place. Adaptive grid, on the other hand, increases the grid resolution around the fire location as shown in Figure 2. At the points where fires occur, adaptive grid reduces cell size to approximately 400 m or one tenth of the static grid size. This provides adaptive grid the capability to distinguish two distinct plumes from the fires. For this reason concentration gradients are much better resolved by the adaptive grid model than by the static grid model. Simulation results for other hours are presented in Appendices.

Another objective of this study was to utilize direct sensitivity method to estimate sensitivity of ozone to NO emissions from fires. We made a comparison between static “brute-force” and adaptive direct sensitivity results. Figures 3 and 4 present sensitivity of ozone concentration to fire emissions as estimated by static and adaptive grids respectively on August 15, 19:00 (GMT). While the fires reduce the ozone concentrations near the source by as much as 8 parts per billion (ppb), they result in an increase by as much as 7 ppb further downwind for this particular time period. Such a distinction between the near and the far field impacts is not so clear in the “brute-force” sensitivities calculated by the static grid model shown in Figure 3. Simulation results for other hours are presented in Appendices.

5.4 Analysis of Results

There are no special measurements taken along the trajectory of the fire plumes during the simulated period. The only data available for evaluation are the routine air quality observations from the existing monitoring network. The differences between new and old model simulation results were very small at the monitoring locations, therefore it was difficult to judge if the new model is performing better than the old model solely based on observations. In the absence of measurements, we performed the following evaluations in the vicinity of the fires.

Comparison of Ozone Estimates

We performed statistical analysis to determine the differences between static and adaptive grid simulation results. For this purpose, we identified the adaptive cells that intersect with each static cell. Figure 5 presents an example for intersection of static grid cell with adaptive cells. For this particular case, there are about 40 adaptive cells that fall in one static cell. For the intersected cells we recorded individual adaptive cell concentrations and also estimated a weighted average, based upon area, in order to compare to static cell values. Note that in this analysis we selected a region where changes in O₃ concentration occurred due to fire events. Adaptive grid O₃ concentrations are very similar to static grid simulation results in the rest of the domain.

Figure 6 presents a scatter plot of O₃ concentration values for static and corresponding adaptive cell values for August 15, 21:00 (GMT). In this figure both average values as well as minimum and maximum values of adaptive cells within each 4×4 km² static cell are shown. One of the important finding in Figure 6 is that O₃ concentrations of adaptive cell averages are very close to static cell results. The correlation coefficient of the regression is 0.9 and has a slope of 0.9 which is an indication of a strong linear relationship between average adaptive and static cell results. However, it should also be noted that adaptive cell averages tends to over predict lower concentrations and under predict higher concentrations as compared to static cell values. In other words, the variation in average adaptive results is slightly smaller than the variation in static cell results. For this particular case, coefficient of variation, which is defined as the ratio of the standard deviation to the mean, is 8.1 percent in adaptive case and 8.6 percent in static case. The coefficient of variation in maximum and minimum values together is slightly greater with a value of 8.9 percent. These values suggest that variability is about the same with maximum-minimum values of adaptive cells having the highest variability. It should be noted however that the number of data for this category is twice the static and average adaptive cells. Another important point is the range of variability. Static grid O₃ concentrations change between 62 ppb and 95 ppb, whereas average adaptive cells range between 63 ppb and 92 ppb. For the max/min values this range is between 62 ppb and 96 ppb. Similar results were obtained for other periods of simulation where fire events were observed and they are provided in Appendices.

Table 3 summarizes the comparison between adaptive and static grids for 20 different hours when fires occurred. As seen in Table 3, the range of variation is similar in adaptive maximum-minimum values and static values. The range is slightly smaller in adaptive averages. Parameters of regression between adaptive averages and static values are also given in Table 3. In most cases (15 out of 20) R² values are greater than or equal to 0.9, and slopes are between 0.9 and 1.04. There are, however, nighttime fire events where R² is less than 0.85 and slope is less than 0.8. In general, it is observed that there is a strong linear relationship between adaptive averages and static values. In 16 cases, the slope of regression is less than 1.0 indicating that the adaptive average O3 concentration is less than the static cell values. These results are in agreement with the study conducted by Jang et al. (1995) where they found that lumped finer-scale grid (i.e., 20km) produced less O3 than coarser grid (i.e., 80km) for equal size area.

Another implication of the differences in adaptive and static predictions is at the local scale. Figure 7 shows O3 concentrations from adaptive and static grid simulations at a cell near the fires for selected time periods. Adaptive cell averages as well as minimum and maximum values of adaptive cells that fall in the 4×4 km² static cell are presented. Adaptive averages are 4 ppb more than static values on the average, and the difference ranges from -2 ppb to +18 ppb. For minimum and maximum adaptive values the average difference from static concentration is +6 ppb, and it ranges from -6 ppb to +28 ppb. These findings suggest that there can be significant differences in O3 between adaptive and static grids at the local scale. For example, one static grid O3 is 47 ppb whereas one of the adaptive cells inside that static cell has a value of 75. This 28 ppb difference may have important implications from a policy perspective.
Comparison of Ozone Sensitivities

We did a similar analysis to compare sensitivity results from static and adaptive simulations. Figure 8 presents the comparison for the selected region on August 15, 21:00 (GMT). As in the case for O₃ predictions, R² and slope values indicate that there is a linear relationship between adaptive averages and static values for sensitivity. However, there is a high variability in individual adaptive cell values as shown by the minimum and maximum sensitivity values. Variation ranges from -8 ppb to +6 ppb for the maximum-minimum adaptive values, whereas it is between -6 ppb and +5 ppb in static grid. For the adaptive averages the range of variation is between -6 ppb and +5 ppb. Similar results were obtained for other periods of simulation where fire events occurred and they are provided in Appendices. Table 4 presents a summary of these events. As seen in Table 4, variability in O₃ sensitivity is smallest in adaptive averages.

Maximum-minimum adaptive values have a higher variability than static values. Table 4 also presents parameters of regression between adaptive averages and static values. It is seen that most of the cases (15 out of 20) have R² values greater than 0.85 and slope values are greater than 0.70. There are several fire events where there is weak correlation between adaptive averages and static values. One R² value is 0.14 at the beginning of a fire. Others are during the nighttime events. In all these cases the sensitivity is mostly negative. The differences in the sensitivities estimated by static and adaptive grids are indicative of the scale-related uncertainty in modeling the impact of prescribed burns.

6 Conclusions

Our objective was to bring current air quality models to a level where they can be used to predict the impact on the surrounding environment of air pollutants emitted from military installations. We improved the models’ ability to capture source-receptor relationships between emissions at local scales and air quality at regional scale. In this project, we focused on the prescribed burning emissions from Fort Benning as a case study. The immediate questions we answered are:

- Can our recently developed techniques bridge the gap between the current state of the models and DoD’s needs of determining the fate of emissions from military operations?

- If so, do the prescribed burning operations have an impact to the air quality in Columbus metropolitan area?

The answer to the first question is positive but the study was inclusive for the second question. Now that the first phase objectives are achieved, follow-on research in a second phase should address the following questions:

- What extensions are necessary for the techniques to be applied to other DoD activities such as aviation, ship and coastal operations?

- Can we develop reliable tools to help site managers not only to plan their operations but adapt them as necessary for minimizing adverse effects to the environment?

The development of this impact analysis technology has many upside potentials. A user-friendly product tailored to DoD needs can be developed, along with a detailed plan for the transfer of this technology to DoD facilities. The technology can be implemented in U.S. EPA’s Community Multiscale Air Quality (CMAQ) model and applied to many other sectors including energy, agriculture and homeland security.

In conclusion, the new model (i.e., MAQSIP enhanced by adaptive grid and sensitivity analysis techniques) can be used for accurate assessment of the air quality impacts of most DoD activities.

Adaptive Grid Modeling for Predicting the Air Quality Impacts of Biomass Burning

Alper Unal and M. Talat Odman

School of Civil and Environmental Engineering, Georgia Institute of Technology, Atlanta, Georgia

1. INTRODUCTION

Wildland fires are essential in creating and maintaining functional ecosystems and achieving other land use objectives (Hardy and Leenhouts, 2001). However, biomass burning produces combustion byproducts that are harmful to human health and welfare (Hardy and Leenhouts, 2001; Battye and Battye, 2002). Guided by the Endangered Species Act (ESA), the Department of Interior (DoI) through the Fish and Wildlife Service (FWS) mandates that some military installations and air force bases in the South-Eastern United States use prescribed burning to recreate the natural fire regimes needed to maintain the health of its native long leaf pine forestland thus protecting the habitat of the endangered Red Cockaded Woodpecker (RCW). Proper management may require as much as 1/3 of the forest to undergo treatment by fire each year. These activities, however, can contribute significantly to already burdened local and regional air pollutant loads. In recognition of the conflicting requirements between the ESA and Clean Air Act (CAA) statutes, the Strategic Environmental Research and Development Program (SERDP), supported by Department of Defense (DoD), initiated a program to determine the effects of biomass burning from military installations. As part of this effort, we focused on determining the effects of biomass burning from military reservation, Fort Benning in Georgia, to the local and regional air quality, specifically, in Columbus metropolitan area.

Fort Benning, which covers an area of approximately 182,000 acres, is located in the lower part of central Georgia and Alabama, six miles southeast of Columbus, Georgia, as shown in Figure 1. Thus emissions from this facility may be affecting the air quality in Columbus, which is reported to violate air quality standards for Ozone (EPD, 2003). The Columbus Environmental Committee is viewing the prescribed burning operation as a potential contributor to the ozone problem. This became a public relations concern for Fort Benning (Larimore, 2000).

Approximately 30,000 acres must be prescribed burned each year at Fort Benning, during the growing season (i.e., March through August). This period falls within the “ozone season.” In order to restore the RCW habitat, longleaf seedlings are planted. Prescribed burnings continue from August through October for site preparation purposes, which also overlaps with the ozone season. These fires reduce unwanted vegetation that would compete with longleaf seedlings. Operational and safety constraints limit the burnings to an average of 300 acres per day (Environmental Management Division, 2000). For example, although an attempt is made to burn all RCW clusters during the growing season it is logistically impossible due to the number of clusters (75-80 annually) and scheduling conflicts with training. Natural firebreaks, such as roads, trails, drains, and creeks dictate the size of burn areas. All these limitations make it necessary to continue the burnings throughout the year. In realization of the Columbus ozone problem, the majority of the burnings (70-75%) were shifted to the January-April period, which is outside the “ozone season.”

Currently, the only external constraint on prescribed burning arises as a result of smoke management concerns. Smoke complaints and the threat of litigation from smoke-related incidents / accidents
are the primary concerns. Fort Benning follows voluntary (not mandated by state or federal government) smoke management guidelines in an effort to minimize the adverse impacts from smoke. An additional concern is the effect of prescribed burning on ozone levels in Columbus. Forest fires produce nitrogen oxide and hydrocarbon emissions that form ozone (Cheng et al., 1998; Battye and Battye, 2002; Ottmar, 2001). These pollutants may be transported downwind, mix with emissions from other sources and contribute to the poor air quality in urban areas. Sulfur dioxide and particulate matter emissions from forest fires are also of concern but, in general, they do not have a direct influence on the urban ozone problem. The ozone alert season is from 1 May through 30 September in Georgia. It is during this season that emissions from prescribed burning operations could affect smog levels in Columbus. In collaboration with the Partnership for a Smog-Free Georgia (PSG), Fort Benning is avoiding prescribed burns when meteorological conditions are conducive to ozone buildup. However, more complex methods are required to identify the real effects of biomass burning from Fort Benning on ozone problem in Columbus region.

Main objective in this study is to improve the ability to model the air quality impacts of biomass burning on the surrounding environment. For this purpose we equipped an advanced air quality model, Multiscale Air Quality Simulation Platform (MAQSIP) (Odman and Ingram, 1996), with two newly developed techniques; Adaptive Grid Modeling, and Direct Sensitivity Analysis to accurately isolate and determine the effects of biomass burning on ozone formation. In this paper we first describe the methods utilized and then discuss the important findings of the study.

2. METHODOLOGY

The atmospheric and chemical modeling systems currently used by various agencies tend to focus on a single scale that seems to be the most relevant to a particular air pollution problem. Global scale models address climate issues while regional scale models are used for the tropospheric ozone, regional haze or acid deposition studies. Urban scale smog models are being replaced with urban-to-regional scale models in most places where transport from other upwind sources play an
important role. On the local scale, models are used to deal with problems such as accidental releases. The domains of local scale models are limited by design; therefore, they cannot be used for regional scale impact studies.

One of the most advanced urban-to-regional scale models is the MAQSIP. Urban-to-regional scale models are used in developing emission control strategies for problems such as urban and regional ozone, acid deposition, or regional haze which is attributed to primary (emitted) and secondary (formed in the atmosphere) fine particulate matter. While these models are equipped with special tools to treat emissions from large power plants (Karamchandani et al., 2000), they lack the ability to resolve emissions from relatively small area sources such as those from prescribed burnings. To account for such area sources, the models rely on grid resolution. Prescribed burnings are performed over areas as small as one square kilometer (approximately 200 acres). This scale is too small for typical regional applications. Therefore, emissions from prescribed fires are blended with emissions from many other sources within the same grid cell of regional scale models. This would make it impossible to conduct an impact study that would target emissions from biomass burnings.

Another limitation of current air quality models is related to numerical errors involved during the simulations. Let us suppose that the grid cell size could be reduced to one square kilometer by using nested-grid techniques (Odman et al., 1997). In that case, a typical prescribed burning unit would cover a single grid cell. The effect of having or not having prescribed burning emissions from a single grid cell would be a small perturbation for air quality models. As the perturbation gets smaller in size, numerical errors that affect the simulation results become more important. The results of an impact study such as the one proposed here would be highly uncertain if the models were used as is. Therefore, urban-to-regional scale models, in their current state, are not very reliable tools for determining the impact of prescribed burning emissions to the surrounding environment.

The study of the impact of biomass burning from DoD facilities requires investigation of the interaction between various scales due to the fact that both the location of the facilities and the lifetimes of emitted pollutants are conducive to long-range transport. Below, we describe a methodology to improve current urban-to-regional scale air quality models with two modeling techniques. These techniques improve representation of the transport and transformation processes over a wide range of scales and provide more reliable source-receptor relationships. The product is a more reliable tool that can predict accurately the ultimate fate of pollutants emitted from specific sources such as DoD facilities.

2.1. Adaptive Grid Modeling

We developed an adaptive grid modeling approach to reduce the uncertainty in air quality predictions. By clustering the grid nodes in regions that would potentially have large errors in pollutant concentrations, the model is expected to generate much more accurate results than the traditional fixed, uniform grid counterparts. The repositioning of grid nodes is performed automatically through the use of a weight function that assumes large values when the curvature (change of slope) of the pollutant fields is large. The nodes are clustered around regions where the weight function bears large values, thereby increasing the resolution where it is needed. Since the number of nodes is fixed, refinement of grid scales in regions of interest is accompanied by coarsening in other regions where the weight function has smaller values. This yields a continuous multiscale grid where the scales change gradually. Unlike nested grids, there are no grid interfaces, which may introduce numerous difficulties due to the discontinuity of grid scales. The availability of computational resources determines the number of grid nodes that can be afforded in any model application. By clustering grid nodes automatically in regions of interest, the adaptive grid technique uses computational resources in an optimal fashion throughout the simulation.

A detailed description of the technique can be found in Srivastava et al. (2000). Here we will not repeat that information; instead, we will try to illustrate the technique and its potential with relevant applications. The adaptive technique was applied to problems with increasing complexity and relevance to air quality modeling. First, it was applied to pure advection tests (Srivastava et al., 2000). In a rotating cone test, the adaptive grid solution was more
accurate than the fixed uniform grid with the same number of grid nodes. The error in maintaining the peak of the cone was only 13% compared to 39% with the fixed grid: an accuracy that could only be achieved by using 22 times more grid nodes with a fixed uniform grid. Srivastava et al. (2001a) conducted a third test with concentric conical puffs of NO, and VOCs reacting in a rotational wind field. The parameters of this problem are such that, after a certain time, ozone levels drop below the background near the base of the conical puffs but they peak near the vertex of the cones. This feature was resolved by the adaptive grid solution while it was completely missed by the uniform fixed grid solution. When nine times more grid nodes were used, the fixed grid was finally able to reveal this feature but not as accurately as the adaptive grid technique.

Next, the adaptive grid technique was applied to the simulation of a power plant plume (Srivastava et al., 2001b). A two dimensional plume with a VOC/NO, emission ratio of 14% was advected with uniform winds and diffused over a background with a VOC/NO, ratio of 35. Other parameters were chosen to make the dispersion as realistic as possible. After about 12 hours of simulation, the composition of the plume was analyzed taking cross sections at various downwind distances. At 10 km downwind, the adaptive grid solution showed a NO, rich, but ozone deficient core. This feature, which is also observed in actual power plant plumes, was completely missing in the uniform grid solution, which artificially diffused the NO, and displayed highest ozone levels at the core of the plume. The adaptive grid, on the other hand, had ozone bulges developing near the plume edges. At a downwind distance of 30 km, these bulges continued to grow as NO, diffused slowly from the core to the edges (at a rate more in line with physical diffusion) and radicals were entrained into the plume. This plume structure started disappearing after about 80 km. At a downwind distance of 135 km, the plume was fully matured with an ozone peak at the center. The peak ozone concentration was larger than one predicted by the fixed uniform grid. A similar evolution of the plume was observed in the fixed uniform grid solution when the number of grid nodes was increased by a factor of nine. However, this solution was about five times more expensive than the adaptive grid solution.

After these and other testing of the algorithm (Odman et al., 2001; Khan et al., 2003), finally an adaptive grid AQM was developed (Odman et al., 2002). The model was applied to an ozone simulation in the Tennessee Valley (Khan and Odman 2003). Ozone results from this application were evaluated and showed significant improvement over those from fixed grid models, even those employing up to four times more grid cells. In several cases the agreement with observations was better compared to fixed grid models. When the reasons were investigated it was found that the complex source-receptor relationships, especially the long-range ones were much better resolved with the adaptive grid.

2.2. Direct Sensitivity Analysis

Sensitivity analysis is essential in determining source-receptor relationships and designing emission control strategies. The traditional “brute-force” method involves running the model several times, each time perturbing one type of emission (e.g., NO, or VOC) from a different source. If the perturbation is small, the brute-force method may not yield accurate sensitivities due to numerical errors propagating in the model. Our group has developed a new and powerful direct sensitivity analysis technique to study the response of air quality to various types of emissions (Yang et al, 1997). Unlike the brute force approach, this technique is not limited by the magnitude of the perturbation and, in theory, it can be used for even infinitesimal changes in emissions. Therefore, the technique has the potential of improving current models to a level where they can be used for impact analysis of relatively small sources such as military installations.

Air quality models are based on the atmospheric diffusion equation:

\[ \frac{\partial c_i}{\partial t} + \nabla \cdot (u c_i) = \nabla \cdot (K \nabla c_i) + R_i + S_i \]  

Here, \( c_i \) is the concentration of the \( i \)th pollutant species, \( u \) describes the velocity field, \( K \) is the diffusivity tensor, \( R_i(c_1, c_2, \ldots) \) is the chemical reaction term and \( S_i \) is a source term for certain types of emissions. The local sensitivity of the
concentration of a species (e.g., ozone) to a certain emission type (e.g., NO, or VOC) from a particular source can be defined as:

\[ s_j(t) = \frac{\partial c_j(t)}{\partial E_j} \]  

(2)

Here, \( s_j \) is the sensitivity of \( c_j \) to emission \( E_j \). Since the sensitivities to different emissions can vary by many orders of magnitude, it is necessary to define semi-normalized sensitivity coefficients, \( \hat{s}_j \).

\[ \hat{s}_j(t) = \frac{\hat{E}_j}{E_j} \frac{\partial c_j(t)}{\partial E_j} \]  

(3)

where \( \hat{E}_j \) is the unperturbed emission field (i.e., without fire). Using direct derivatives of Equation (1) the following equation can be obtained for sensitivities.

\[
\frac{\partial \hat{s}_j}{\partial t} = -\nabla (u \hat{s}_j) + \nabla (K \nabla \hat{s}_j) + J_{\lambda} \hat{s}_j \hat{\delta}_j + \frac{\partial R_i}{\partial E_j} \\
+ \frac{\partial \hat{s}_j}{\partial E_j} - \nabla (u c_i) \hat{\delta}_j + \nabla (K V \hat{c}_i) \hat{\delta}_j
\]  

(4)

Here, \( \hat{s}_j \) is the semi-normalized sensitivity coefficient, \( J_{\lambda} \) is the Jacobian matrix, \( c_i \) is a scaling variable with a nominal value of 1, and \( \hat{\delta}_j \) is a binary variable (either 1 or 0).

The similarity between Equations (1) and (4) allows us to use the same or very similar numerical solution techniques and calculate local sensitivities to emission sources simultaneously along with the species concentrations. This also makes the implementation of the technique in any model relatively straightforward. The technique is also computationally efficient because several of these sensitivities (the number being limited by available core memory) can be calculated simultaneously with a fractional increase in CPU time. The emission sources can be discerned by type as point, area, mobile, or biogenic, and by composition such as SO\(_2\), NO\(_x\), or VOC. Also, the location of the emission source can be specified, for example, as the boundaries of a DoD facility (to the grid scale resolution). The technique would predict the sensitivity of air quality at any desired location in the modeling domain (e.g., sensitivity of ozone concentrations at a downwind urban center) to a fractional change in the emissions from the source of interest.

The technique has been evaluated in an application to the Southern California where the sensitivities of ozone concentrations to the domain wide reductions of mobile and area sources of NO\(_x\) were compared to a brute-force method (Yang et al., 1997). This technique was used in an integrated modeling system focusing, simultaneously, on ozone, particulate matter and acid deposition (Boylan, et al., 2001). We investigated the sensitivity of particulate matter concentrations to the reductions of SO\(_2\) and NO\(_x\) emissions in the Southern Appalachian Mountains region. We also investigated the sensitivity of ozone concentrations to NO\(_x\) and VOC emissions from different states, using state boundaries as sub-regions. As part of that project, we compared our method to the brute-force approach for ozone sensitivities to domain wide NO\(_x\) and VOC emissions. The general agreement between the direct sensitivity and the brute-force method shows that the former is a reliable tool. Whenever we observed differences, we were able to relate the difference to the numerical errors associated with the brute force technique and show that the direct sensitivity method yields results that are more accurate.

3. AIR QUALITY SIMULATIONS

3.1. Episode Selection

The episode selection is based primarily on the availability and quality of meteorological and emissions data and the impact potential of prescribed burns at Fort Benning on regional air quality. As part of Fall Line Air Quality Study (FAQS), we have already simulated several episodes during summer of 1996 and 2000 in Georgia using MM5 meteorological model and SMOKE emissions model. The ideal scenario for our case study is one with southeasterly winds, biomass burning performed at Fort Benning and high ozone levels observed at Columbus. Based upon contacts with Land Management Branch at Fort Benning we obtained the locations, date, and time of biomass burning efforts (Westbury, 2002). There were
biomass burnings at Fort Benning between August 15 and August 18, 2000. Also, ozone levels in Columbus region were over the standards at least four times and prevailing winds were southeasterly during the same period. Therefore, we decided to simulate the period from August 15 through August 18, 2000.

3.2. Data Preparation

Data preparation efforts included meteorological and emissions data preparation as well as post-processing. Meteorological data were obtained from FAQS. Detailed information on meteorological data preparation is given elsewhere (Hu et al., 2003). Similarly, emissions data were obtained from FAQS study. More information on emissions data can be obtained elsewhere (Unal et al., 2003; Hu et al., 2003). For biomass burning emissions, First Order Fire Effects Model (FOFEM) Version 5, developed by Intermountain Fire Sciences Laboratory was utilized. In this model, fuel type was assumed as natural fuel with long leaf pine trees. For some of the pollutants, such as speciated VOCs and NOx, emission factors provided by Battye and Battye (2002) were utilized.

3.3. Static Grid Simulation

To verify model efforts, a 4x4 km Static Grid version of the MAQSIP model was used in simulation for the selected episode. Lambert Conformal projection with parameters of 30°N, 60°N, and 90°W, centered at 40°N and 90°W, was utilized for the domain. The 4x4 grid has 102 columns and 78 rows with 13 vertical layers. The results of the Static Grid run were compared with outputs from the FAQS project for the same location and time period. The comparison showed that Static Grid results were similar to FAQS results. A separate run was made with emissions including fire as well. The difference between the concentrations of these two simulations yields an adaptive grid "brute-force".

3.4. Adaptive Grid Simulation

The adaptive grid also used the same domain definitions as for the static grid. In adaptive runs, inert fire tracer concentrations are used to calculate the weight function that drives the adaption. The tracer is assumed to be a product of the fires at Fort Benning emitted at the same rate as NO emissions from fire. The tracer is transported and deposited the same way as other fire species but is non-reactive. Two different runs were made with the Adaptive Grid model. These runs include: one run with base emissions; and one run with base emissions plus fire emissions, which also has the direct sensitivity calculations. In both runs, the grid adapted to the same fire tracer, therefore the grids are identical in both simulations. The difference between the concentrations of these two simulations yields an adaptive grid "brute-force".

4. RESULTS AND DISCUSSIONS

First, we compared the Adaptive Grid model with the Static Grid version. The tracer concentrations predicted by the two models as a result of fires at Fort Benning are shown in Figures 2 and 3. On August 15, 2000 at 19:00 UTM, two different fires happened at two different cells of the Static Grid, which is clearly observed in Figure 2. The fire to the south is emitting at a higher rate than the northern one, since the area burned is almost 1.5 times bigger. It should be noted that Static Grid distributes emissions uniformly to the whole cell area where the fire takes place.

Figure 3 presents concentrations of the inert fire tracer as well as the grid orientation around Fort Benning at 19:00. From Figure 3 it is clear that Adaptive model increases the grid resolution around the fire at Fort Benning. Figure 3 also gives an enlargement of the figure where adaption occurs. At the points where fires occur, adaptive grid size reduces almost to 400 m by 400 m, one tenth of the Static grid size. As seen in Figure 3, two distinct plumes from fires at Fort Benning are clearly visible during the simulation. Note that concentration gradients are much better resolved by the Adaptive Grid model than by the Static Grid model.

Another way of evaluating the results of an air quality simulation is to compare them to air quality observations from the existing monitoring network. Unfortunately, there are no measurements along the trajectory of the fire plumes during the simulated period. Special air quality measurements are required for this purpose.

Researchers at Georgia Tech are currently collecting air quality data in the vicinity of Fort Benning as part of a study supported by SERDP to characterize pollutants emitted from prescribed burning (Baumann et al., 2003). Data from this study were not available for the selected episode. However, as part of our future work we are planning to utilize these data for evaluation of our model.

Recall that another objective of this study was to utilize direct sensitivity method to estimate sensitivity of ozone to NO emissions from fires. For this purpose, we equipped our Adaptive Grid model with direct sensitivity technique. Figure 4 presents this sensitivity in the afternoon of August 15. While the fires reduce the ozone concentrations near the source by as much as 16 ppb, they result in an increase by as much as 7 ppb further downwind. Such a distinction between the near and far field impacts is not so clear in the "brute-force" sensitivities calculated by the Static Grid model, as shown in Figure 5. The impacts of the fires on the air quality in Columbus are minimal on this particular day.

5. CONCLUSIONS AND FUTURE WORK

The objective of this study is to determine the air quality impacts of biomass burning on the surrounding environment. Fort Benning military reservation, Georgia, was utilized as a case study.

Current air quality models lack the capability of dealing with multi-scale air quality problems. In this study we utilized an Adaptive Grid model which inherently has the ability of continuous multiscale gridding. This method also reduces uncertainty in air quality predictions by clustering the grid nodes in regions that would potentially have large errors in pollutant concentrations.

We successfully implemented the Adaptive Grid model in our study and observed that concentration gradients are much better resolved by the Adaptive Grid model than the Static Grid version. This is due to the fact that Adaptive Grid model has 400m by 400m grid cells at locations where fires occur compared to 4km by 4km Static Grid cells.

It should be noted that we did not have the air quality observations data to compare our simulation results for the selected episode. However, we are going to compare our results to a database that is being developed by researchers at Georgia Tech.

Another important aspect of this study is to implement direct sensitivity technique to our Adaptive Grid model. We successfully achieved this task and showed that our results are superior to the results of "brute-force" technique that we utilized with the Static Grid version. The Static Grid cannot resolve the difference between the near and far field impacts as Adaptive Grid does. It was found that the impact of the fires ranged from 16 ppb reduction to 7 ppb increase in ozone concentrations. The impact of the fires on the air quality in Columbus area was minimal during the selected period.

Overall, we successfully incorporated two new techniques into a regional-scale air quality model. This study showed that Adaptive Grid model equipped with direct sensitivity method can accurately determine the impact of small-scale emission events on the air quality in larger scales. We showed that these techniques can be utilized to determine the impact of biomass burning.

Adaptive Grid Modeling for Predicting the Air Quality

Impacts of Biomass Burning

Alper Unal and M. Talat Odman

Georgia Institute of Technology, Atlanta, Georgia

Abstract

The objective of this study is to improve the ability to model the air quality impacts of biomass burning on the surrounding environment. The focus is on prescribed burning emissions from a military reservation, Fort Benning in Georgia, and their impact on local and regional air quality. The approach taken in this study is to utilize two new techniques we recently developed: 1) Adaptive grid modeling and 2) Direct sensitivity analysis. We equipped an advanced air quality model, MAQSIP, with these techniques and conducted regional scale air quality simulations. Grid adaptation reduces the grid sizes in areas that have rapid changes in concentration gradients consequently the results are much more accurate than those of traditional static grid models. Direct sensitivity analysis calculates the rate of change of concentrations with respect to emissions. This enabled us to isolate the effect of emissions from a specific source such as biomass burning.

The adaptive grid simulation estimated large variations in $O_3$ concentrations within 4×4 km$^2$ cells for which the static grid estimates a single average concentration. In one cell, the maximum of adaptive grid values was 28 ppb higher than the static grid value. On the other hand, the average of the adaptive grid $O_3$ concentrations generally agreed well with the static grid concentration.

The differences between adaptive average and static grid values of $O_3$ sensitivities were more
pronounced. The sensitivity of \( O_3 \) to fire is difficult to estimate using the brute-force method with coarse scale (4x4 km\(^2\)) static grid models. The qualitative analysis shows that the adaptive grid model equipped with the DDM method can estimate the sensitivity of \( O_3 \) to relatively small perturbations such as a prescribed burn more accurately. The static grid can not resolve the difference between the near and far field impacts as adaptive grid does. It was found that the impact of the fires ranged from almost 50 ppb reduction to 8 ppb increase in ozone concentrations. However, the impact of the fires on the air quality in Columbus area was minimal during the selected period.

1. INTRODUCTION

Wildland fires are essential in creating and maintaining functional ecosystems and achieving other land use objectives (Hardy and Leenhouts, 2001). However, biomass burning produces combustion byproducts that are harmful to human health and welfare (Hardy and Leenhouts, 2001; Battye and Battye, 2002). Guided by the Endangered Species Act (ESA), the Department of Interior (DoI) through the Fish and Wildlife Service (FWS) mandates that some military installations and air force bases in the South-Eastern United States use prescribed burning to recreate the natural fire regimes needed to maintain the health of its native long leaf pine forestland thus protecting the habitat of the endangered Red Cockaded Woodpecker (RCW). Proper management may require as much as 1/3 of the forest to undergo treatment by fire each year. These activities, however, can contribute significantly to already burdened local and regional air pollutant loads. In recognition of the conflicting requirements between the ESA and Clean Air Act (CAA) statutes, the Strategic Environmental Research and Development Program (SERDP), supported by Department of Defense (DoD), initiated a program to determine the
effects of biomass burning from military installations. As part of this effort, we focused on
determining the effects of biomass burning from military reservation, Fort Benning in Georgia,
to the local and regional air quality, specifically, in Columbus metropolitan area.

Fort Benning, which covers an area of approximately 182,000 acres, is located in the lower part
of central Georgia and Alabama, six miles southeast of Columbus, Georgia. Thus emissions from
this facility may be affecting the air quality in Columbus, which is reported to violate air quality
standards for Ozone (EPD, 2003). The Columbus Environmental Committee is viewing the
prescribed burning operation as a potential contributor to the ozone problem. This became a
public relations concern for Fort Benning (Larimore, 2000).

Approximately 30,000 acres must be prescribed burned each year at Fort Benning, during the
growing season (i.e., March through August). This period falls within the “ozone season.” In
order to restore the RCW habitat, longleaf seedlings are planted. Prescribed burnings continue
from August through October for site preparation purposes, which also overlaps with the ozone
season. These fires reduce unwanted vegetation that would compete with longleaf seedlings.
Operational and safety constraints limit the burnings to an average of 300 acres per day
(Environmental Management Division, 2000). For example, although an attempt is made to burn
all RCW clusters during the growing season it is logistically impossible due to the number of
clusters (75-80 annually) and scheduling conflicts with training. Natural firebreaks, such as
roads, trails, drains, and creeks dictate the size of burn areas. All these limitations make it
necessary to continue the burnings throughout the year. In realization of the Columbus ozone
problem, the majority of the burnings (70-75%) were shifted to the January-April period, which
is outside the “ozone season.”
Currently, the only external constraint on prescribed burning arises as a result of smoke management concerns. Smoke complaints and the threat of litigation from smoke-related incidents / accidents are the primary concerns. Fort Benning follows voluntary (not mandated by state or federal government) smoke management guidelines in an effort to minimize the adverse impacts from smoke. An additional concern is the effect of prescribed burning on ozone levels in Columbus. Forest fires produce nitrogen oxide and hydrocarbon emissions that form ozone (Cheng et al., 1998; Battye and Battye, 2002; Ottmar, 2001). These pollutants may be transported downwind, mix with emissions from other sources and contribute to the poor air quality in urban areas. Sulfur dioxide and particulate matter emissions from forest fires are also of concern but, in general, they do not have a direct influence on the urban ozone problem. The ozone alert season is from 1 May through 30 September in Georgia. It is during this season that emissions from prescribed burning operations could affect smog levels in Columbus. In collaboration with the Partnership for a Smog-Free Georgia (PSG), Fort Benning is avoiding prescribed burns when meteorological conditions are conducive to ozone buildup. However, more complex methods are required to identify the real effects of biomass burning from Fort Benning on ozone problem in Columbus region.

Main objective in this study is to improve the ability to model the air quality impacts of biomass burning on the surrounding environment. For this purpose we equipped an advanced air quality model, Multiscale Air Quality Simulation Platform (MAQSIP) (Odman and Ingram, 1996), with two newly developed techniques; Adaptive Grid Modeling, and Direct Sensitivity Analysis to accurately isolate and determine the effects of biomass burning on ozone formation. In this paper we first describe the methods utilized and then discuss the important findings of the study.
2. METHODOLOGY

The atmospheric and chemical modeling systems currently used by various agencies tend to focus on a single scale that seems to be the most relevant to a particular air pollution problem. Global scale models address climate issues while regional scale models are used for the tropospheric ozone, regional haze or acid deposition studies. Urban scale smog models are being replaced with urban-to-regional scale models in most places where transport from other upwind sources play an important role. On the local scale, models are used to deal with problems such as accidental releases. The domains of local scale models are limited by design; therefore, they cannot be used for regional scale impact studies.

One of the most advanced urban-to-regional scale models is the MAQSIP. Urban-to-regional scale models are used in developing emission control strategies for problems such as urban and regional ozone, acid deposition, or regional haze which is attributed to primary (emitted) and secondary (formed in the atmosphere) fine particulate matter. While these models are equipped with special tools to treat emissions from large power plants (Karamchandani et al, 2000), they lack the ability to resolve emissions from relatively small area sources such as those from prescribed burnings. To account for such area sources, the models rely on grid resolution. Prescribed burnings are performed over areas as small as one square kilometer (approximately 200 acres). This scale is too small for typical regional applications. Therefore, emissions from prescribed fires are blended with emissions from many other sources within the same grid cell of regional scale models. This would make it impossible to conduct an impact study that would target emissions from biomass burnings.

Another limitation of current air quality models is related to numerical errors involved during the
simulations. Let us suppose that the grid cell size could be reduced to one square kilometer by using nested-grid techniques (Odman et al., 1997). In that case, a typical prescribed burning unit would cover a single grid cell. The effect of having or not having prescribed burning emissions from a single grid cell would be a small perturbation for air quality models. As the perturbation gets smaller in size, numerical errors that affect the simulation results become more important. The results of an impact study such as the one proposed here would be highly uncertain if the models were used as is. Therefore, urban-to-regional scale models, in their current state, are not very reliable tools for determining the impact of prescribed burning emissions to the surrounding environment.

The study of the impact of biomass burning from DoD facilities requires investigation of the interaction between various scales due to the fact that both the location of the facilities and the lifetimes of emitted pollutants are conducive to long-range transport. Below, we describe a methodology to improve current urban-to-regional scale air quality models with two modeling techniques. These techniques improve representation of the transport and transformation processes over a wide range of scales and provide more reliable source-receptor relationships. The product is a more reliable tool that can predict accurately the ultimate fate of pollutants emitted from specific sources such as DoD facilities.

2.1. **Adaptive Grid Modeling**

We developed an adaptive grid modeling approach to reduce the uncertainty in air quality predictions. By clustering the grid nodes in regions that would potentially have large errors in pollutant concentrations, the model is expected to generate much more accurate results than the traditional fixed, uniform grid counterparts. The repositioning of grid nodes is performed
automatically through the use of a weight function that assumes large values when the curvature
(change of slope) of the pollutant fields is large. The nodes are clustered around regions where
the weight function bears large values, thereby increasing the resolution where it is needed. Since
the number of nodes is fixed, refinement of grid scales in regions of interest is accompanied by
coarsening in other regions where the weight function has smaller values. This yields a
continuous multiscale grid where the scales change gradually. Unlike nested grids, there are no
grid interfaces, which may introduce numerous difficulties due to the discontinuity of grid scales.
The availability of computational resources determines the number of grid nodes that can be
afforded in any model application. By clustering grid nodes automatically in regions of interest,
the adaptive grid technique uses computational resources in an optimal fashion throughout the
simulation.

A detailed description of the technique can be found in Srivastava et al. (2000). The adaptive
technique was applied to problems with increasing complexity and relevance to air quality
modeling. First, it was applied to pure advection tests (Srivastava et al., 2000). In a rotating cone
test, the adaptive grid solution was more accurate than the fixed uniform grid with the same
number of grid nodes. The error in maintaining the peak of the cone was only 13% compared to
39% with the fixed grid: an accuracy that could only be achieved by using 22 times more grid
nodes with a fixed uniform grid. Srivastava et al. (2001a) conducted a third test with concentric
conical puffs of NO\textsubscript{x} and VOCs reacting in a rotational wind field. The parameters of this
problem are such that, after a certain time, ozone levels drop below the background near the base
of the conical puffs but they peak near the vertex of the cones. This feature was resolved by the
adaptive grid solution while it was completely missed by the uniform fixed grid solution. When
nine times more grid nodes were used, the fixed grid was finally able to reveal this feature but
not as accurately as the adaptive grid technique.

Next, the adaptive grid technique was applied to the simulation of a power plant plume (Srivastava et al., 2001b). A two dimensional plume with a VOC/NO\textsubscript{x} emission ratio of 14% was advected with uniform winds and diffused over a background with a VOC/NO\textsubscript{x} ratio of 35. Other parameters were chosen to make the dispersion as realistic as possible. After about 12 hours of simulation, the composition of the plume was analyzed taking cross sections at various downwind distances. At 10 km downwind, the adaptive grid solution showed a NO\textsubscript{x} rich, but ozone deficient core. This feature, which is also observed in actual power plant plumes, was completely missing in the uniform grid solution, which artificially diffused the NO\textsubscript{x} and displayed highest ozone levels at the core of the plume. The adaptive grid, on the other hand, had ozone bulges developing near the plume edges. At a downwind distance of 30 km, these bulges continued to grow as NO\textsubscript{x} diffused slowly from the core to the edges (at a rate more in line with physical diffusion) and radicals were entrained into the plume. This plume structure started disappearing after about 80 km. At a downwind distance of 135 km, the plume was fully matured with an ozone peak at the center. The peak ozone concentration was larger than one predicted by the fixed uniform grid. A similar evolution of the plume was observed in the fixed uniform grid solution when the number of grid nodes was increased by a factor of nine. However, this solution was about five times more expensive than the adaptive grid solution.

After these and other testing of the algorithm (Odman et al., 2001; Khan et al., 2003), finally an adaptive grid AQM was developed (Odman et al., 2002). The model was applied to an ozone simulation in the Tennessee Valley (Khan and Odman 2003). Ozone results from this application were evaluated and showed significant improvement over those from fixed grid models, even those employing up to four times more grid cells. In several cases the agreement with
observations was better compared to fixed grid models. When the reasons were investigated it was found that the complex source-receptor relationships, especially the long-range ones were much better resolved with the adaptive grid.

2.2. **Direct Sensitivity Analysis**

Sensitivity analysis is essential in determining source-receptor relationships and designing emission control strategies. The traditional "brute-force" method involves running the model several times, each time perturbing one type of emission (e.g., NO\textsubscript{x} or VOC) from a different source. If the perturbation is small, the brute-force method may not yield accurate sensitivities due to numerical errors propagating in the model. Our group has developed a new and powerful direct sensitivity analysis technique to study the response of air quality to various types of emissions (Yang et al., 1997; Hakami et al., 2003). Unlike the brute force approach, this technique is not limited by the magnitude of the perturbation and, in theory, it can be used for even infinitesimal changes in emissions. Therefore, the technique has the potential of improving current models to a level where they can be used for impact analysis of relatively small sources such as military installations.

Air quality models are based on the atmospheric diffusion equation:

\[
\frac{\partial c_i}{\partial t} + \nabla \cdot (u c_i) = \nabla \cdot (K \nabla c_i) + R_i + S_i
\]  

(1)

Here, \(c_i\) is the concentration of the \(i\)th pollutant species, \(u\) describes the velocity field, \(K\) is the diffusivity tensor, \(R_i(c_1, c_2, ...)\) is the chemical reaction term and \(S_i\) is a source term for certain types of emissions. The local sensitivity of the concentration of a species (e.g., ozone) to a certain emission type (e.g., NO\textsubscript{x} or VOC) from a particular source can be defined as:
Here, $s_{ij}$ is the sensitivity of $c_i$ to emission $E_j$. Since the sensitivities to different emissions can vary by many orders of magnitude, it is necessary to define semi-normalized sensitivity coefficients, $s^*_ij$.

$$s^*_ij(t) = \frac{\partial c_i(t)}{\partial E_j}$$

where $\bar{E}_j$ is the unperturbed emission field (i.e., without fire). Using direct derivatives of Equation (1) the following equation can be obtained for sensitivities.

$$\frac{\partial s^*_ij}{\partial t} = -\nabla \left( u^*_{ij} \right) + \nabla \left( K \nabla s^*_ij \right) + J_{ik} s^*_{kj} + \frac{\partial R_{ij}}{\partial E_j} + \frac{\partial S_{ij}}{\partial E_j} - \nabla \left( u_{ij} \right) \delta_{ij} + \nabla \left( K \nabla c_{ij} \right) \delta_{ij}$$

Here, $s^*_ij$ is the semi-normalized sensitivity coefficient, $J_{ik}$ is the Jacobian matrix, $\varepsilon_j$ is a scaling variable with a nominal value of 1, and $\delta_{ij}$ is a binary variable (either 1 or 0).

The similarity between Equations (1) and (4) allows us to use the same or very similar numerical solution techniques and calculate local sensitivities to emission sources simultaneously along with the species concentrations. This also makes the implementation of the technique in any model relatively straightforward. The technique is also computationally efficient because several of these sensitivities (the number being limited by available core memory) can be calculated simultaneously with a fractional increase in CPU time. The emission sources can be discerned by type as point, area, mobile, or biogenic, and by composition such as SO$_2$, NO$_x$, or VOC. Also, the location of the emission source can be specified, for example, as the boundaries of a DoD...
facility (to the grid scale resolution). The technique would predict the sensitivity of air quality at any desired location in the modeling domain (e.g., sensitivity of ozone concentrations at a downwind urban center) to a fractional change in the emissions from the source of interest.

The technique has been evaluated in an application to the Southern California where the sensitivities of ozone concentrations to the domain wide reductions of mobile and area sources of NOx were compared to a brute-force method (Yang et al., 1997). This technique was used in an integrated modeling system focusing, simultaneously, on ozone, particulate matter and acid deposition (Boylan, et al., 2001). We investigated the sensitivity of particulate matter concentrations to the reductions of SO2 and NOx emissions in the Southern Appalachian Mountains region. We also investigated the sensitivity of ozone concentrations to NOx and VOC emissions from different states, using state boundaries as sub-regions. As part of that project, we compared our method to the brute-force approach for ozone sensitivities to domain wide NOx and VOC emissions. The general agreement between the direct sensitivity and the brute-force method shows that the former is a reliable tool. Whenever we observed differences, we were able to relate the difference to the numerical errors associated with the brute force technique and show that the direct sensitivity method yields results that are more accurate.

3. AIR QUALITY SIMULATIONS

3.1. Episode Selection

The episode selection is based primarily on the availability and quality of meteorological and emissions data as well as the impact potential of prescribed burns at Fort Benning on regional air quality. As part of Fall Line Air Quality Study (FAQS), we have already simulated several episodes during summer of 1999 and 2000 in Georgia using MM5 meteorological model and
SMOKE emissions model. The ideal scenario for our case study is one with southeasterly winds, biomass burning performed at Fort Benning and high ozone levels observed at Columbus. Based upon contacts with Land Management Branch at Fort Benning we obtained the locations, date, and time of biomass burning efforts (Westbury, 2002). There were biomass burnings at Fort Benning between August 15 and August 18, 2000. Also ozone levels in Columbus region were over the standards at least four times and prevailing winds were southeasterly during the same period. Therefore, we decided to simulate the period from August 15 through August 18, 2000.

3.2. Data Preparation

Data preparation efforts included meteorological and emissions data preparation as well as post-processing. Meteorological data were obtained from FAQS. Detailed information on meteorological data preparation is given elsewhere (Hu et al., 2003). Similarly emissions data were obtained from FAQS study. More information on emissions data can be obtained elsewhere (Unal et al., 2003; Hu et al., 2003). For biomass burning emissions First Order Fire Effects Model (FOFEM) Version 5, developed by Intermountain Fire Sciences Laboratory was utilized. In this model fuel type was assumed as natural fuel with long leaf pine trees. For some of the pollutants, such as speciated VOCs and NOx, emission factors provided by Battye and Battye (2002) were utilized.

3.3. Static Grid Simulations

To verify model efforts, a 4×4 km static grid version of the MAQSIP model was used in simulation for the selected episode. Lambert Conformal projection with parameters of 30°N, 60°N, and 90°W, centered at 40°N and 90°W, was utilized for the domain. The 4×4 grid has 102 columns and 78 rows with 13 vertical layers. The results of the static grid run were compared
with outputs from the FAQS project for the same location and time period. The comparison showed that static grid results were similar to FAQS results. A separate run was made with emissions including fire as well. The difference between the concentrations of these two simulations yields static grid “brute-force”.

3.4. **Adaptive Grid Simulations**

The adaptive grid also used the same domain definitions as for the static grid. In adaptive runs inert fire tracer concentrations are used to calculate the weight function that drives the adaption. The tracer is assumed to be a product of the fires at Fort Benning emitted at the same rate as NO emissions from fire. The tracer is transported and deposited the same way as other fire species but it is non reactive. Two different runs were made with the adaptive grid model. These runs include: one run with base emissions; and one run with base emissions plus fire emissions, which also has the direct sensitivity calculations. In both runs the grid adapted to the same fire tracer, therefore the grids are identical in both simulations. The difference between the concentrations of these two simulations yields an adaptive grid “brute-force”. DDM sensitivity results were compared with “brute-force” and it was observed that differences were within the bounds of previously reported differences (Hakami *et al.*, 2003). Only DDM sensitivities will be used hereafter.

4. **RESULTS**

First we compared the adaptive grid model with the static grid model. The tracer concentrations calculated by the two models as a result of fires at Fort Benning on August 15, 2000 at 19:00 Greenwich Mean Time (GMT) are shown in Figures 1 and 2. During this period two different fires happened at two different locations. The fire to the south is emitting at a higher rate than the
northern one since the area burnt is almost 1.5 times bigger. The location of these fires can be seen in both static and adaptive simulation results.

One of the significant differences between these simulations is the fact that static grid distributes emissions uniformly to the 4-km by 4-km cell area where the fire takes place. Adaptive grid, on the other hand, increases the grid resolution around the fire location as shown in Figure 2. At the points where fires occur, adaptive grid reduces cell size to 400m by 400 m or one tenth of the static grid size. This provides adaptive grid the capability to distinguish two distinct plumes from the fires. For this reason concentration gradients are much better resolved by the adaptive grid model than by the static grid model.

Another objective of this study was to utilize direct sensitivity method to estimate sensitivity of ozone to NO emissions from fires. We made a comparison between static "brute-force" and adaptive direct sensitivity results. Figures 3 and 4 present sensitivity of ozone concentration to fire emissions as estimated by static and adaptive grids respectively, in the afternoon of August 15, 19:00 PM (UTM). While the fires reduce the ozone concentrations near the source by as much as 8 ppb, they result in an increase by as much as 7 ppb further downwind for this particular time period. Such a distinction between the near and the far field impacts is not so clear in the "brute-force" sensitivities calculated by the static grid model, as shown in Figure 3.

5. DATA ANALYSIS

5.1. Comparison of Ozone Estimates

We performed statistical analysis to determine the differences between static and adaptive simulation results. For this purpose, we identified the adaptive cells that intersect with each static cell. Figure 5 presents an example for intersection of static grid cell with adaptive cells. For this
particular case, there are about 40 adaptive cells that fall in one static cell. For the intersected
cells we recorded individual adaptive cell concentrations and also estimated a weighted average,
based upon area, in order to compare to static cell values. Note that in this analysis we selected a
region where changes in O₃ concentration occurred due to fire events. Adaptive grid O₃
concentrations are very similar to static grid simulation results in the rest of the domain.

Figure 6 presents a scatter plot of O₃ concentration values for static and corresponding adaptive
cell values for August 15, 21:00 PM (GMT). In this figure both average values as well as
minimum and maximum values of adaptive cells within each 4-km by 4-km static cell are shown.

One of the important finding in Figure 6 is that O₃ concentrations of adaptive cell averages are
very close to static cell results. The correlation coefficient of the regression is 0.9 and has a slope
of 0.9 which is an indication of a strong linear relationship between average adaptive and static
cell results. However, it should also be noted that adaptive cell averages tends to over predict
lower concentrations and under predict higher concentrations as compared to static cell values.

The variation in average adaptive results is slightly lower than static cell results. For this
particular case, coefficient of variation, which is defined as the ratio of the standard deviation to
the mean, is 8.1 percent in adaptive case and 8.6 percent in static case. The coefficient of
variation in maximum and minimum values together is slightly greater with a value of 8.9
percent. These values suggest that variability is about the same with maximum-minimum values
of adaptive cells having the highest variability. It should be noted however that the number of
data for this category is twice the static and average adaptive cells. Another important point is
the range of variability. Static grid O₃ concentrations change between 62 ppb and 95 ppb,
whereas average adaptive cells range between 63 ppb and 92 ppb. For the max/min values this
range is between 62 ppb and 96 ppb. Similar results were obtained for other periods of
simulation where fire events were observed.

Table 1 summarizes the comparison between adaptive and static grids for 20 different hours when fires occurred. As seen in Table 1, the range of variation is similar in adaptive maximum/minimum values and static values. The range is slightly smaller in adaptive averages. Parameters of regression between adaptive averages and static values are also given in Table 1. In most cases (15 out of 20) $R^2$ values are greater than or equal to 0.9, and slopes are between 0.9 and 1.04. There are, however, nighttime fire events where $R^2$ is less than 0.85 and slope is less than 0.8. In general, it is observed that there is a strong linear relationship between adaptive averages and static values. In 16 cases, the slope of regression is less than 1.0 indicating that the adaptive average $O_3$ concentration is less than the static cell values. These results are in agreement with the study conducted by Jang et al. (1995) where they found that lumped finer-scale grid (i.e., 20km) produced less $O_3$ than coarser grid (i.e., 80km) for equal size area.

Another implication of the differences in adaptive and static predictions is at the local scale. Figure 7 shows $O_3$ concentrations from adaptive and static grid simulations at a cell near the fires for selected time periods. Adaptive cell averages as well as minimum and maximum values of adaptive cells that fall in the 4-km by 4-km static cell are presented. Adaptive averages are 4 ppb more than static values on the average, and the difference ranges from -2 ppb to 18 ppb. For minimum and maximum adaptive values the average difference from static concentration is +6 ppb, and it ranges from -6 ppb to 28 ppb. These findings suggest that there can be significant differences in $O_3$ between adaptive and static grids at the local scale. For example, one static grid $O_3$ is 47 ppb whereas one of the adaptive cells inside that static cell has a value of 75. This 28 ppb difference may have important implications from a policy perspective.
5.2. Comparison of Ozone Sensitivities

We did a similar analysis to compare sensitivity results from static and adaptive simulations. Figure 8 presents the comparison for the selected region on August 15, 21:00 (UTM). As in the case for O₃ predictions, R² and slope values indicate that there is a linear relationship between adaptive averages and static values for sensitivity. However, there is a high variability in individual adaptive cell values as shown by the minimum and maximum sensitivity values. Variation ranges from -8 ppb to 6 ppb for the maximum-minimum adaptive values, whereas it is between -6 ppb to 5 ppb in static grid. For the adaptive averages the range of variation is between -6 ppb to 5 ppb. Similar results were obtained for other periods of simulation where fire events were occurred. Table 2 presents a summary of these events. As seen in Table 2, variability in O₃ sensitivity is smallest in adaptive averages. Maximum-minimum adaptive values have a higher variability than static values. Table 2 also presents parameters of regression between adaptive averages and static values. It is seen that most of the cases (15 out of 20) have R² values greater than 0.85 and slope values are greater than 0.70. There are several fire events where there is weak correlation between adaptive averages and static values. One R² value is 0.14 at the beginning of a fire. Others are during the nighttime events. In all these cases the sensitivity is mostly negative. The differences in the sensitivities estimated by static and adaptive grids are indicative of the scale-related uncertainty in modeling the impact of prescribed burns.

6. CONCLUSIONS AND FUTURE WORK

The objective of this study was to determine the air quality impacts of biomass burning on the surrounding environment. Fort Benning military reservation, Georgia, was utilized as a case study.
Current air quality models lack the capability of dealing with multi-scale air quality problems. In this study we utilized an adaptive grid model which inherently has the ability of continuous multiscale gridding. This method also reduces uncertainty in air quality predictions by clustering the grid nodes in regions that would potentially have large errors in pollutant concentrations.

We successfully implemented the adaptive grid model in our study and observed that concentration gradients are much better resolved by the adaptive grid model than the static grid version. This is due to the fact that adaptive grid model has 400m by 400m grid cells at locations where fires occur compared to 4km by 4km static grid cells.

The adaptive grid simulation estimated large variations in O₃ concentrations within 4x4 km² cells for which the static grid estimates a single average concentration. In one cell, the maximum of adaptive grid values was 28 ppb higher than the static grid value. On the other hand, the average of the adaptive grid O₃ concentrations generally agreed well with the static grid concentration. The correlation coefficient between adaptive average and static grid values was about 0.9. The average O₃ of adaptive cells had a slightly smaller range than the O₃ of corresponding static cells with lower values on the upper end and higher values on the lower end.

The differences between adaptive average and static grid values of O₃ sensitivities were more pronounced. The sensitivity of O₃ to fire is difficult to estimate using the brute-force method with coarse scale (4x4 km²) static grid models. Qualitative analysis showed that the adaptive grid model equipped with the DDM method can estimate the sensitivity of O₃ to relatively small perturbations such as a prescribed burn more accurately. The static grid cannot resolve the difference between the near and far field impacts as adaptive grid does. It was found that the impact of the fires ranged from almost 50 ppb reduction to 8 ppb increase in ozone. 
concentrations. However, the impact of the fires on the air quality in Columbus area was minimal during the selected period. These findings have to be supported with quantitative analysis in the future. A monitoring program is underway to collect air quality data to support our modeling efforts.

Overall, we successfully incorporated two new techniques into a regional-scale air quality model. This study showed that adaptive grid model equipped with direct sensitivity method can accurately determine the impact of small-scale emission events on the air quality in larger scales. We showed that these techniques can be utilized to determine the impact of biomass burning.
