Date Approved: April 17, 2008
To Dad. I miss you.
ACKNOWLEDGEMENTS

The step from acquiring to generating knowledge is without a doubt one of the most significant challenges I have faced, and without the support, patience and guidance of several people, it would have been unsurpassable. To all of them I owe my deepest gratitude.

First and foremost, I want to express my deepest gratitude to Yang for all that help and support, academic and otherwise, given to me through this years. His guidance, patience, advice and encouragement have played an essential role in my first steps as a researcher. I am indebted to him more than he knows.

Many thanks go also to Chris Heil, Doron Lubinsky, Guillermo Goldsztein and Steven McLaughlin for serving on my committee. To them I also owe some gratitude for amazingly interesting times inside a classroom, and at times, also mathematical and colloquial conversations in hallways and offices.

It is delightful to have the opportunity to pay tribute to the entire staff of the School of Mathematics of Georgia Tech. A special mention goes to Genola Turner, Sharon McDowell and Christy Dalton. I also would like to recognize the efficiency and diligence of the IT Support Team, who have successfully guided me on the resolution of all and every technical problem I have confronted here.

There are many mathematicians who have provided me intellectually stimulating insights into areas of Mathematics as diverse as Harmonic Analysis, Number Theory, Algebraic Geometry and Dynamical Systems. My profound gratitude to Howie Weiss, Matt Baker, Sinan Güntürk, Özgür Yilmaz, John Benedetto, Alex Powell and Ingrid Daubechies.

I have found also very rewarding to be part of the community of gradstudents
of the School of Mathematics. Both for mutual feedback on mathematical topics, as well as for endless hours of some of the greatest (and funniest) conversations I have ever had, I thank Luis Hernández, Guido Kampel, Trevis Litherland, Hua Xu, Eliane Traldi, Csaba Biro, Teena Carroll and Ben Webb. A very special mention should be made of Alex Grigo, who had the misfortune to have his office next to mine for four long years, and has had to endure me more than any other fellow gradstudent.

I would also like to thank the School of Mathematics to trust me the organization of the High School Math Competition. It has been an honor and a pleasure to share that task with Prof. Rena Brakebill, as well as with Nguyen Truong, Mitch Keller, Cindy Phillips and Nicole Larsen.

Nobody gets to gradschool without having been first and undergrad, and I feel compelled to pay a tribute to some of the men and women who inspired me to follow the path of the mathematician. From them, I owe a special gratitude to Pedro Rodríguez, William Alvarado, Santiago Cambronero and Asdrubal Duarte.

Definitively, I wouldn’t be here if not by my family. To my mom and all that group of people who endure me while I was growing up, who supported and encouraged me through the years. Infinite thanks to all of you. To my dad, a special mention, he was the person who nurtured my interest for sciences and mathematics since my early years. I will grieve his loss for the rest of my life.

Last but not least, I honestly think there is nobody on earth I owe more gratitude than to Susana, the woman who was brave enough to marry me and remain with me through the years. She has been the one on my side through the happy times, as well as through the tough ones. For loving me as much as she does (at times more than what I deserve), for supporting me at every moment, and just for being there when I need her, I thank her more than words can fairly express.

No acknowledgement list is ever exhaustive. To those people whose names I have overlooked, I apologize for my omission.

SUMMARY

In this thesis we consider two different problems in quantization theory. During the first part we discuss the so called Bennett’s White Noise Hypothesis, introduced to study quantization errors of different schemes. Under this hypothesis, one assumes that the reconstruction errors of different channels can be considered as uniform, independent and identically distributed random variables.

We prove that in the case of uniform quantization errors for frame expansions, this hypothesis is in fact false. Nevertheless, we also prove that in the case of fine quantization, the errors of different channels are asymptotically uncorrelated, validating, at least partially, results on the computation of the mean square error of reconstructions that were obtained through the assumption of Bennett’s hypothesis.

On the second part of this thesis, we will introduced a new scalar quantization scheme, called a $\beta\alpha$-encoder. We analyse its robustness with respect to the quantizer imperfections. This scheme also induces a challenging dynamical system. We give partial results dealing with the ergodicity of this system.
CHAPTER I

A BRIEF INTRODUCTION TO QUANTIZATION

1.1 Quantization and A/D Conversion

Information technology introduced through the 20th century and whose rapid development continues to this day has allowed mankind the ability to process, store, transmit and retrieve large volumes of data in digital form, this is, finite strings of digits, elements of a finite alphabet.

Up to some extend, this represents a limitation: Digital data is in essence discrete, while an important percentage of the information involved in the daily human life comes from sources that are by nature analog. Therefore there is an intrinsic need to transform this analog information into digital data. This is what we call analog-to-digital (A/D) conversion.

Analog information seldomly requires an exact reproduction, as measurements need to be known up to certain precision, and images as well as sounds have much more detail than that meeting our senses. Thus, as long as the technology available is able to reproduce such information within the appropriate range of accuracy (to be defined according to the application), some of the original information can be sacrificed.

As some detail can be ignored from the original data, given the limitation of sensors, whether it’s our sensory organs or electronic sensors, we may model our information as a bandlimited function \( f \), this is, the support of its Fourier Transform \( \hat{f} \) is in \([−\Omega, \Omega]\) for some finite value \( \Omega \in \mathbb{R} \). Without loss of generality, we will assume \( \Omega = \pi \).

The Sampling Theorem, also called Shannon-Nyquist Theorem, solves, at least up
to some extent, this problem.

**Theorem 1.1 (Sampling Theorem)** Let $f : \mathbb{R} \to \mathbb{R}$ be a bandlimited function such that $\hat{f}$ is supported in $[-\pi, \pi]$. Let $\lambda > 1$, and $\varphi \in L^1(\mathbb{R})$ such that $\hat{\varphi}$ is continuous and satisfies

\[
\hat{\varphi}(\xi) = \begin{cases} 
1 & \text{if } |\xi| \leq \pi, \text{ and} \\
0 & \text{if } |\xi| \geq \lambda \pi.
\end{cases}
\]

Then, the following equality holds in the Cesàro mean for all $t$.

\[
f(t) = \frac{1}{\lambda} \sum_{n \in \mathbb{Z}} f\left(\frac{n}{\lambda}\right) \varphi\left(t - \frac{n}{\lambda}\right).
\]

A more detailed discussion of this theorem is given in Appendix A. Assuming that the fixed function $\varphi$ can be computed for any value, $f$ can be perfectly reconstructed from its samples $x_n = f(n\lambda^{-1})$. Therefore, the analog signal $f$ can be expressed in terms of the discrete set $\{x_n\}_{n \in \mathbb{Z}}$. Nevertheless, the samples themselves come from the real numbers, and they are still in nature analog, as their digital representation is almost certainly, infinite and aperiodic. Therefore, there is still the need to transform each of the values $x_n$ to a finite digital expression $\tilde{x}_n$, and certainly, there is a need to represent just finitely many of such values. The process of converting these infinitely many samples to a finite collection of finite strings of digits is called quantization.

### 1.2 Quantizers and General Definitions

Once a sampling process has been applied to an analog signal $f$, a quantizer or quantization scheme is the process of taking the collection $\{x_n\}_{n \in \mathbb{Z}}$ and encode them into $\{\tilde{x}_n\}_{n \in \mathcal{J}}$ (for some discrete set $\mathcal{J}$) at a low cost in such a way that a reproduction can be recovered from such collection with as high quality as possible, where the cost of the process and the quality of the reproduction are to be defined depending on the specific application.

In a more formal setting, a quantizer can be defined as consisting of a source space $\mathcal{X}$ (assumed to be a metric space), a density distribution $g$ over $\mathcal{X}$, a set of cells
\( S = \{ S_i : i \in I \} \) for some index set \( I \) (we assume that \( S \) is a partition of \( X \), and \( I \) is a finite or countable set), a set of output values or levels \( C = \{ y_i | i \in I \} \) together with a quantizer function defined by \( Q(x) = y_i \) for \( x \in S_i \). Unless otherwise stated, \( C \) is assumed to be a set of finite binary strings.

It is intuitively clear that given any source space \( X \) and density distribution \( g \), it should be possible to define a wide range of quantizers. How to choose the most appropriate depends therefore on the inherited concepts of cost and reproduction quality.

Generally, a signal is quantized to be stored or transmitted in digital form, and therefore, the length in bits of the quantized output should be optimized. Hence, it is wise to define the cost, or bit rate of the quantizer as

\[
R(Q) = \sum_{i \in I} \ell(y_i) P(S_i), \tag{1.1}
\]

where \( \ell(y_i) \) is the length in bits of the binary representation of \( y_i \), and \( P(S_i) \) the probability of a source input to belong to \( S_i \).

On the other hand, the quality of the quantizer can be defined as how accurate the reconstruction of a source input is. Every \( y_i \in C \) has a unique reconstruction value \( x_i \in X \) associated with it. A useful way to define accuracy is to define a distortion measure \( d(x, x_i) = |x - x_i|^2 \). It is possible then to quantify the average distortion of the system as

\[
D(Q) = \mathcal{E}[d(X, Q(X))] = \sum_{i \in I} \int_{S_i} d(x, x_i) g(x) dx, \tag{1.2}
\]

and thus, a small average distortion translate in a high quality of the quantization scheme and vice versa.

### 1.3 Pulse Code Modulation (PCM)

One of the first quantization schemes is pulse code modulation or PCM. In this case, \( S \) is a partition of \( \mathbb{R} \) into disjoint intervals. For every interval \( S_i[a_i, a_{i+1}] \) in \( S \), the
quantization rule $Q$ assigns to each $x$ in such cell a preset value (called levels) $y_i \in S_i$. The values $\{a_i\}$ are called the thresholds of the scheme.

A PCM quantizer is said to be uniform if the levels $y_i$ are equispaced, say $\Delta$ apart, and the thresholds are midway between adjacent levels. If an infinite number of levels is allowed, then all cells $S_i$ width equal to $\Delta$. If only a finite number of levels is allowed, then all but two of the cells will have width $\Delta$ and the two outermost will be semi-infinite. $\Delta$ is said to be the quantization step.

Throughout this thesis, when we refer to PCM, we refer to the uniform pulse code modulation quantization scheme, where $C = \Delta Z$, with $\Delta > 0$ to be specified and the quantization rule given by

$$Q_{\Delta}(t) := \left\lfloor \frac{t}{\Delta} + \frac{1}{2} \right\rfloor \Delta.$$  \hspace{1cm} (1.3)

In other words $t$ is replaced by the value in $C$ closest to $t$. 

4
PART I

White Noise Hypothesis for Uniform Quantization Errors of Frame Expansions
CHAPTER II

BASICS OF FRAME THEORY

When a signal is processed, it is generally practical to quantize the samples in blocks (either of fixed or variable length) instead of sample by sample. If such blocks are considered to have a fixed length, this is called vector quantization. This is the case we will analyze through the first part of this thesis.

If we assume that samples are consistently grouped in blocks of \( d \) scalars, we can consider the input space as \( \mathbb{R}^d \) instead of \( \mathbb{R} \).

Once an input or signal is given, it is often necessary to make an atomic decomposition of it using a given set of atoms, or dictionary \( \{v_j\} \). In this approach, a signal \( x \) is represented as a linear combination of \( \{v_j\} \),

\[
x = \sum_j c_j v_j.
\]

In practice \( \{v_j\} \) is a finite set. Furthermore, for the purpose of error correction, recovery from data erasures or robustness, redundancy is built into \( \{v_j\} \), i.e. it has more elements than needed. Instead of a true basis, \( \{v_j\} \) is chosen to be a frame. We may without loss of generality assume that this dictionary has \( N \) elements, with \( N \geq d \), and thus, we will denoted by \( \{v_j\}_{j=1}^N \).

2.1 Frames

As it was already discussed, one of the basic processes an input undergoes on most applications of A/D conversion is that of discretization, in which the input space is by nature analog and its samples have to be described through the use of a finite dictionary. Due to the potential presence of noise, it is advisable to implement some sort of redundancy in such process to facilitate better reconstruction of the input later.
If the input space is a finite-dimension vector space, intuitively this can be seen as representing the signal as linear combination of the elements of some finite set that generates the complete space, in a way, an over-complete basis, a set that spans the complete space, as a basis, nevertheless, the linear independence condition is omitted. This is, informally speaking, what a frame is. A more formal definition of a frame is given below.

**Definition 2.1 (Frame)** An ordered set \( \{v_j\}_{j \in I} \) of elements of a Hilbert space \( H \) is called a frame if the index set \( I \) is finite or countable and there are constants \( A, B > 0 \) such that

\[
A \|x\|^2 \leq \sum_{j \in I} |(x \cdot v_j)|^2 \leq B \|x\|^2, \tag{2.1}
\]

where \( x \cdot y \) denotes the inner product of the vectors \( x \) and \( y \).

The numbers \( A \) and \( B \) in the definition are called lower and upper frame bounds respectively. The largest \( A > 0 \) and smallest \( B > 0 \) satisfying the frame inequalities on \( (2.1) \) for all \( x \in H \) are called the optimal frame bounds. Also, if \( A = B \) then the frame is said to be tight.

It is clear that an orthonormal basis \( \{e_j\}_{j \in J} \) of a Hilbert space is a frame for such space. One of the nicest properties of such basis is the fact that for every \( x \in H \), the following reconstruction formula is satisfied:

\[
x = \sum_{j \in J} (x \cdot e_j)e_j.
\]

Such property is in general not satisfied for a frame. Nevertheless, for any frame \( \{v_j\}_{j \in I} \) it is always possible to derive an auxiliary frame \( \{u_j\}_{j \in I} \) such that for every \( x \in H \),

\[
x = \sum_{j \in I} (x \cdot v_j)u_j = \sum_{j \in I} (x \cdot u_j)v_j. \tag{2.2}
\]

For a detailed proof of this fact, see [9, §5.6]. If \( \{v_j\}_{j \in I} \) and \( \{u_j\}_{j \in I} \) satisfy \( (2.2) \), then they are said to be each other’s dual frame.
2.2 Useful Facts about Finite Frames

All the facts mentioned on the previous section apply to general frames, finite or not. On this section we exploit some of the specific characteristics of finite frames. For this purpose, we consider the Hilbert space $H$ to have a finite dimension $d$, and without loss of generality we call it $\mathbb{R}^d$. Our frame has $N$ elements and it is denoted by $\{v_j\}_{j=1}^N$.

For encoding purposes, given the ease of reconstruction of $x$ introduced by (2.2), it is desirable to find a fast way to compute the data $\{x \cdot v_j\}_{j=1}^N$. Note that if we set the matrix $F = [v_1, v_2, \ldots, v_N]$, this is, the $d \times N$ matrix having the vectors $v_j$ as columns, and set $y = [x \cdot v_1, x \cdot v_2, \ldots, x \cdot v_N]^T$, then $y = F^T x$.

Lemma 2.1 $\{v_j\}_{j=1}^N$ is a frame if and only if $F$ has rank $d$.

As $F$ has full rank ($F^T x = 0$ implies $x = 0$), then $FF^T$ is a positive definite matrix, and therefore, invertible, and all its eigenvalues are positive. Furthermore, $FF^T$ is a symmetric matrix, therefore one can choose an orthonormal basis $\{e_j\}_{j=1}^d$ for $\mathbb{R}^d$ such that each $e_j$ is an eigenvector of $FF^T$. Besides, note that

$$(FF^T)^{-1} F y = (FF^T)^{-1} FF^T x = x. \quad (2.3)$$

In this setting, $F$ is called the matrix representation of the frame $\{v_j\}_{j=1}^N$, and for practical purposes, we should not make any distinction between $F$ and $\{v_j\}_{j=1}^N$. Let’s call $G = (FF^T)^{-1} F$, and denote it as $G = [u_1, u_2, \ldots, u_N]$, where $u_j$ are the columns of $G$, then note that

$$x = GF x = Gy = \sum_{j=1}^N (x \cdot v_j) u_j, \quad (2.4)$$

an thus, $F$ and $G$ are mutual dual frames. We will call $G$ the canonical dual frame of $F$.

Call $0 < \lambda_{\min} = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_d = \lambda_{\max}$ the eigenvalues of $FF^T$. Now, suppose that $\{e_j\}_{j=1}^d$ is an orthonormal basis of $\mathbb{R}^d$, where each $e_j$ is the eigenvector...
of $FF^T$ associated with $\lambda_j$. Note that if $x = a_1e_1 + \cdots + a_de_d$, then
\[
x^TFF^Tx = (a_1e_1 + \cdots + a_de_d) \cdot (a_1\lambda_1e_1 + \cdots + a_d\lambda_de_d)
= a_1^2\lambda_1 + a_2^2\lambda_2 + \cdots + a_d^2\lambda_d
\leq \lambda_{\max}(a_1^2 + a_2^2 + \cdots + a_2^2)
= \lambda_{\max}\|x\|^2.
\]
The equality is achieved for $x = e_d$. Similarly $\lambda_{\min}\|x\|^2 \leq x^TFF^Tx$, where the equality is achieved for $x = e_1$. Finally, note that as $F^Tx = [x \cdot v_1, \ldots, x \cdot v_N]^T$, then
\[
x^TFF^Tx = (F^Tx)^TF^Tx = \|F^Tx\|^2 = \sum_{j=1}^{N} |x \cdot v_j|^2.
\]
Thus,
\[
\lambda_{\min}\|x\|^2 \leq \sum_{j=1}^{N} |x \cdot v_j|^2 \leq \lambda_{\max}\|x\|^2,
\]
and therefore $\lambda_{\min}$ and $\lambda_{\max}$ are the optimal frame bounds for $F$.

If $F$ is a tight frame, then $\lambda = \lambda_{\min} = \lambda_{\max}$ and $G = \lambda^{-1}F$, and the reconstruction formula become
\[
x = \frac{1}{\lambda} \sum_{j=1}^{N} (x \cdot v_j)v_j.
\]

2.3 Frames and Vector Quantization

Given a frame $\{v_j\}_{j=1}^{N}$ and its canonical dual frame $\{u_j\}_{j=1}^{N}$, one would desire to use the coefficients $\{x \cdot v_j\}_{j=1}^{N}$ and (2.4) to obtain a perfect reconstruction of $x$. Nevertheless, as it has been already discussed, such demand is implausible when using a digital media. Instead, the coefficients are to be quantized. We consider a uniform PCM quantization of each individual coefficient, and thus we use the quantized data $\{Q_{\Delta}(x \cdot v_j)\}_{j=1}^{N}$, where $Q_{\Delta}$ is defined by (1.3), obtaining an imperfect reconstruction
\[
\tilde{x} = \sum_{j=1}^{N} Q_{\Delta}(x \cdot v_j)u_j.
\]

8
This raises the following question: How good is the reconstruction? This question has been studied in terms of both the worst case error and the mean square error (\textit{MSE}), see e.g. [20]. Note that the error from the reconstruction is

\[
x - \tilde{x} = \sum_{j=1}^{N} \tau_{\Delta} (x \cdot v_j) u_j,
\]

where \( \tau_{\Delta}(t) := t - Q_{\Delta}(t) = \left( \{ \frac{t}{\Delta} + \frac{1}{2} \} - \frac{1}{2} \right) \Delta \), with \{ \cdot \} denoting the fractional part.

While an \textit{a priori} error bound is relatively straightforward to obtain, the \textit{mean square error} \( \text{MSE} := \mathcal{E}(\|x - \tilde{x}\|^2) \), assuming certain probability distribution for \( x \), is much harder. To simplify the problem, the so-called \textit{White Noise Hypothesis (WNH)}, is employed by engineers and mathematicians in this area (see e.g. [3, 2, 20]).

In Chapter 3 we will review the \textbf{WNH}, the \textit{a priori} error bound and previous results about the \textbf{MSE} obtained under such hypothesis. Later, in Chapter 4 we will give a closer look to the \textbf{WNH} and the results obtained through it.
CHAPTER III

THE WHITE NOISE HYPOTHESIS

3.1 Historical Background

The WNH is often called Bennett’s White Noise Assumption [3, 2]. Bennett studied quantization error (distortion) in his fundamental paper [4] in the scalar setting.

The WNH asserts the following:

- Each $\tau_\Delta (x \cdot v_j)$ is uniformly distributed in $[-\Delta/2, \Delta/2)$; hence it has mean 0 and variance $\Delta^2/12$.

- $\{\tau_\Delta (x \cdot v_j)\}_{j=1}^N$ are independent random variables.

Bennett demonstrated that under the assumption that the scalar random variable has a smooth density, the quantization error behaves like uniformly distributed “random noise” when $\Delta$ is small, resulting in the MSE to be approximately $\Delta^2/12$. Bennett also studied quantization errors in the nonuniform quantization setting, which can often be reduced to the uniform setting by the use of companders. The current interest in the WNH stems from the study of vector quantization, in which several correlated signals are quantized simultaneously such as in our setting. A vast literature on vector quantization and on vector quantization errors exist, and for an excellent and comprehensive survey on vector quantization see Gray and Neuhoff [22].

A weaker form of the WNH, which states that the error components are approximately uncorrelated in the high resolution setting, i.e. when $\Delta$ is small, is often found in engineering literatures without rigorous proofs (see [18] and the discussion in [43]).

A rigorous proof of this weaker form of the WNH was first given in Viswanathan and Zamir [43]. More precisely, they proved that if two random variables $X, Y$ have
a joint density function then \( \frac{1}{\Delta^2} \mathcal{E}(\tau_\Delta(X)\tau_\Delta(Y)) \longrightarrow 0 \) as \( \Delta \to 0 \). Viswanathan and Zamir also proved similar results in the nonuniform quantization setting, under much stronger assumptions.

### 3.2 A Priori Error Bounds and MSE under the WNH

In this section we derive \( a \ priori \) error bounds and a formula for the MSE under the WNH. These results are not new. We include them for self-containment. We use the following settings throughout this section: Let \( \{v_j\}_{j=1}^N \) be a frame in \( \mathbb{R}^d \) with corresponding frame matrix \( F = [v_1, v_2, \ldots, v_N] \). The eigenvalues of \( FF^T \) are \( 0 < \lambda_{\min} = \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_d = \lambda_{\max} \). Let \( \{u_j\}_{j=1}^N \) be the canonical dual frame with corresponding matrix \( G = (FF^T)^{-1}F \). For any \( x = \sum_{j=1}^N (x \cdot v_j) u_j \), using the quantization alphabet \( C = \Delta \mathbb{Z} \) we have the PCM quantized reconstruction

\[
\tilde{x} = \sum_{j=1}^N Q_\Delta (x \cdot v_j) u_j.
\]

**Proposition 3.1** For any \( x \in \mathbb{R}^d \) we have

\[
\|x - \tilde{x}\| \leq \frac{1}{2} \sqrt{\frac{N}{\lambda_{\min}}} \Delta.
\]  

(3.1)

If in addition \( \{v_j\}_{j=1}^N \) is a tight frame with frame constant \( \lambda \), then

\[
\|x - \tilde{x}\| \leq \frac{1}{2} \sqrt{\frac{N}{\lambda}} \Delta.
\]  

(3.2)

**Proof.** We have

\[
x - \tilde{x} = \sum_{j=1}^N \tau_\Delta (x \cdot v_j) u_j = Gy,
\]

where \( y = [\tau_\Delta (x \cdot v_1), \ldots, \tau_\Delta (x \cdot v_N)]^T \). Thus \( \|x - \tilde{x}\|^2 = y^T G^T G y \leq \rho(G^T G) \|y\|^2 \)

where \( \rho(\cdot) \) denotes the spectral radius. Now

\[
\rho(G^T G) = \rho(G G^T) = \rho((FF^T)^{-1}) = \frac{1}{\lambda_{\min}}.
\]

Observe that \( |\tau_\Delta (x \cdot v_j)| \leq \Delta/2 \). Thus \( \|y\|^2 \leq N(\Delta/2)^2 \). This yields an \( a \ priori \) error bound (3.1). The bound (3.2) is an immediate corollary.
Proposition 3.2 Under the WNH, the MSE is

\[ \mathcal{E}(\|x - \bar{x}\|^2) = \frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1} = \frac{\Delta^2}{12} \sum_{j=1}^{N} \|u_j\|^2. \]  

(3.3)

In particular, if \( \{v_j\}_{j=1}^{N} \) is a tight frame with frame constant \( \lambda \), then

\[ \mathcal{E}(\|x - \bar{x}\|^2) = \frac{d}{12} \Delta^2. \]  

(3.4)

**Proof.** Denote \( G^T G = [b_{ij}]_{i,j=1}^{N} \) and again let \( y = [\tau_{\Delta}(x \cdot v_1), \ldots, \tau_{\Delta}(x \cdot v_N)]^T \).

Note that with the WNH, \( \mathcal{E}(y_i y_j) = \mathcal{E}(\tau_{\Delta}(x \cdot v_i) \tau_{\Delta}(x \cdot v_j)) = (\Delta^2/12) \delta_{ij} \). Now \( x - \bar{x} = G y \) and hence

\[ \mathcal{E}(\|x - \bar{x}\|^2) = \mathcal{E}(y^T G^T G y) = \sum_{i,j=1}^{N} b_{ij} \mathcal{E}(y_i y_j) = \sum_{i=1}^{N} b_{ii} \frac{\Delta^2}{12} = \frac{\Delta^2}{12} \text{tr}(G^T G). \]

Finally, \( \text{tr}(G^T G) = \sum_{j=1}^{N} \|u_j\|^2 \), and

\[ \text{tr}(G^T G) = \text{tr}(G G^T) = \text{tr}((F F^T)^{-1}) = \sum_{j=1}^{d} \lambda_j^{-1}. \]  

\[ \blacksquare \]

Note that using (3.3) the MSE for quantization decreases by a factor of 4 if we decrease \( \Delta \) by a factor of 2. This amounts to an increase in signal to noise ratio of approximately 6dB \( (10 \log_{10} 4 \approx 6) \). This is often referred to as the 6dB-per-bit-rule.

**Remark:** The MSE formulae (3.3) and (3.4) still hold if the independence of \( \{\tau_{\Delta}(x \cdot v_j)\}_{j=1}^{N} \) in the WNH is replaced with the weaker condition of uncorrelation.
CHAPTER IV

A CLOSER LOOK AT THE WNH

4.1 Legitimacy of the WNH

The WNH asserts that the error components \( \{ \tau_{\Delta} (x \cdot v_j) \}_{j=1}^{N} \) are independent and identically distributed random variables. Intuitively this cannot be true if \( N > d \). This is indeed the case in general.

**Theorem 4.1** Let \( X \in \mathbb{R}^d \) be an absolutely continuous random vector. Let \( \{ v_j \}_{j=1}^{N} \) be nonzero vectors in \( \mathbb{R}^d \) with \( N > d \). Then the random variables \( \{ \tau_{\Delta} (X \cdot v_j) \}_{j=1}^{N} \) are not independent.

**Proof.** Let \( F \) be the frame matrix for the frame \( \{ v_j \} \). Then \( \text{dim}(\text{range}(F^T)) \leq d \), and therefore \( L(\text{range}(F^T)) = 0 \) where \( L \) is the Lebesgue measure on \( \mathbb{R}^N \). Let \( Y = [Y_1, \ldots, Y_N]^T := F^T X \), and let \( \hat{Y} = [Q_{\Delta}(Y_1), \ldots, Q_{\Delta}(Y_N)]^T \) be the quantized \( Y \). Denote \( Z = Y - \hat{Y} = [Z_1, \ldots, Z_N]^T \). Note that \( Y_j = v_j \cdot X \), so each \( Y_j \) is absolutely continuous, and therefore so is each \( Z_j \). If \( \{ Z_j \} \) are independent, then \( Z \) must be absolutely continuous.

Now, Set \( \Omega := \text{range}(F^T) + \Delta Z^N \). Then \( L(\Omega) = 0 \) because \( \Delta Z^N \) is a countable set. However, \( Z \) takes values in \( \Omega \) so \( P(Z \in \Omega) = 1 \). This contradicts the absolute continuity of \( Z \).

\[\blacksquare\]

**Remark:** Actually, for Theorem 4.1 to hold we only need to assume that \( X \) has an absolutely continuous component, i.e. \( X = X_c + X_s \) where \( X_c \neq 0 \) is absolutely continuous and \( X_s \) is singular. However, the theorem can fail without the absolute continuity condition, even if each component of \( X \) may be absolutely continuous.
The simplest example is to take $X = [X, -X]^T$ where $X$ is any random variable and $v_1 = [1, 1]^T$ and $v_2 = [1, -1]^T$.

Even when $N = d$ the WNH holds only under rather strict conditions.

**Proposition 4.2** Let $X = [X_1, \ldots, X_m]^T$ be a random vector in $\mathbb{R}^m$ whose distribution has density function $g(x_1, \ldots, x_m)$.

1. The error components $\{\tau_\Delta (X_j)\}_{j=1}^m$ are independent if and only if there exist complex numbers $\{\beta_j(n) : 1 \leq j \leq m, n \in \mathbb{Z}\}$ such that

$$
\hat{g} \left( \frac{a_1}{\Delta}, \ldots, \frac{a_m}{\Delta} \right) = \beta_1(a_1) \cdots \beta_m(a_m)
$$

for all $[a_1, \ldots, a_m]^T \in \mathbb{Z}^m$.

2. Let $h_j(t)$ be the marginal density of $X_j$. Then $\{\tau_\Delta (X_j)\}_{j=1}^m$ are identically distributed if and only if

$$
\sum_{n \in \mathbb{Z}} h_j(t - n\Delta) = H(t) \quad a.e.
$$

for some $H(t)$ independent of $j$. They are uniformly distributed on $[-\Delta/2, \Delta/2]$ if and only if $H(t) = 1/\Delta$ a.e..

**Proof.** To prove (1) denote $I_\Delta = [-\Delta/2, \Delta/2]$. We first observe that $Y = [\tau_\Delta (X_1), \ldots, \tau_\Delta (X_m)]^T$ has a density

$$
G(y) := \sum_{a \in \mathbb{Z}^m} g(y - \Delta a)
$$

for $y \in I_\Delta^m$. The density $G(y)$ is periodic with period $\Delta$, and it is well known that its Fourier series is given by $G(y) = \sum_{a \in \mathbb{Z}^m} c_a e^{2\pi i \frac{a}{\Delta} \cdot y}$, where $c_a = \hat{g} \left( \frac{a}{\Delta} \right)$. But $\{Y_j\}_{j=1}^m$ are independent if and only if on $I_\Delta^m$ we have $g(y_1, \ldots, y_m) = g_1(y_1) \cdots g_m(y_m)$. This happens if and only if

$$
\hat{g} \left( \frac{a_1}{\Delta}, \frac{a_2}{\Delta}, \ldots, \frac{a_m}{\Delta} \right) = h_1 \left( \frac{a_1}{\Delta} \right) h_2 \left( \frac{a_2}{\Delta} \right) \cdots h_m \left( \frac{a_m}{\Delta} \right)
$$
for all \( \mathbf{a} = [a_1, \ldots, a_m]^T \in \mathbb{Z}^m \), with \( h_j(\xi) = \hat{g}_i(\xi) \). This part of the theorem is proved by setting \( \beta_j(n) = h_j(n) \).

The proof of (2) follows directly from the fact that the density of \( \tau_\Delta(X_j) \) is \( \sum_{n \in \mathbb{Z}} h_j(t - n\Delta) \) for \( t \in I_\Delta \).

Proposition 4.2 puts strong constraints on the distribution of \( \mathbf{x} \) for the WNH to hold. Let \( \mathbf{X} \in \mathbb{R}^d \) be a random vector with joint density \( f(\mathbf{x}) \). Let \( \{\mathbf{v}_j\}_{j=1}^d \) be linearly independent, and let \( \mathbf{Y} = [\mathbf{X} \cdot \mathbf{v}_1, \mathbf{X} \cdot \mathbf{v}_2, \ldots, \mathbf{X} \cdot \mathbf{v}_d]^T \). Then the joint density of \( \mathbf{Y} \) is \( g(y) = |\text{det}(F)|^{-1}f((F^T)^{-1}y) \) where \( F = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_d] \). Thus, both the independence and the identical distribution assumptions in the WNH, even for \( N = d \), will be false unless very exact conditions are met. For instance, if we take \( \mathbf{X} \) to be Gaussian and \( F \) to be unitary, then the independence property is satisfied only when \( F \) diagonalizes the covariance matrix of \( \mathbf{X} \).

**Corollary 4.3** Let \( \mathbf{X} \in \mathbb{R}^d \) be a random vector with joint density \( f(\mathbf{x}) \) and \( \{\mathbf{v}_j\}_{j=1}^d \) be linearly independent vectors in \( \mathbb{R}^d \). Let \( \mathbf{Y} = F^T \mathbf{X} = [\mathbf{X} \cdot \mathbf{v}_1, \ldots, \mathbf{X} \cdot \mathbf{v}_N]^T \) and \( g(y) = |\text{det}(F)|^{-1}f((F^T)^{-1}y) \) where \( F = [\mathbf{v}_1, \ldots, \mathbf{v}_d] \).

1. \( \{\tau_\Delta(Y_j)\}_{j=1}^d \) are independent random variables if and only if there exist complex numbers \( \{\beta_j(n) : 1 \leq j \leq d, n \in \mathbb{Z}\} \) such that

   \[
   \hat{g} \left( \frac{a_1}{\Delta}, \ldots, \frac{a_d}{\Delta} \right) = \beta_1(a_1) \cdots \beta_d(a_d) \tag{4.3}
   \]

   for all \( [a_1, \ldots, a_d]^T \in \mathbb{Z}^d \).

2. Let \( h_j(t) = \int_{\mathbb{R}^d} g(x_1, \ldots, x_{j-1}, t, x_{j+1}, \ldots, x_d) \, dx_1 \cdots dx_{j-1} \, dx_{j+1} \ldots dx_d \). Then \( \{\tau_\Delta(X_j)\}_{j=1}^d \) are identically distributed if and only if \( \sum_{n \in \mathbb{Z}} h_j(t - n\Delta) = H(t) \) a.e. for some \( H(t) \) independent of \( j \). They are uniformly distributed on \( [-\frac{\Delta}{2}, \frac{\Delta}{2}] \) if and only if \( H(t) = 1/\Delta \) a.e.
Proof. We only have to observe that \( g(y) \) is the density of \( Y \) and that \( h_j \) is the marginal density of \( Y_j \). The corollary now follows directly from the theorem.

From a practical point of view, with coarse quantization the \text{MSE} of quantization errors cannot be estimated simply by (3.3). Thus the ”6-dB-per-bit” rule may not apply. We shall demonstrate this with numerical results. However, with high resolution quantization the formula (3.3) becomes increasingly accurate. We show this in the next section.

4.2 Asymptotic Behavior of Errors: Linear Independence Case

In many practical applications such as music CD, fine quantizations with 16 bits or more have been adopted. Although the \text{WNH} is not valid in general, with fine quantizations we prove here that a weaker version of the \text{WNH} is close to being valid, which yields an asymptotic formula for the PCM quantized \text{MSE}. Our result here strengthen an asymptototic result in [43].

We again consider the same setup as before. Let \( \{v_j\}_{j=1}^N \) be a frame in \( \mathbb{R}^d \) with corresponding frame matrix \( F = [v_1, v_2, \ldots, v_N] \). The eigenvalues of \( FF^T \) are \( \lambda_{\text{max}} = \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_d = \lambda_{\text{min}} > 0 \). Let \( \{u_j\}_{j=1}^N \) be the canonical dual frame with corresponding matrix \( G = (FF^T)^{-1}F \). For any \( x \in \mathbb{R}^d \) we have \( x = \sum_{j=1}^N (x \cdot v_j) u_j \).

Using the quantization alphabet \( \mathcal{A} = \Delta \mathbb{Z} \) we have the PCM reconstruction (2.6). Note that \( \hat{x} = \hat{x}(\Delta) \) as it depends on \( \Delta \). With the \text{WNH} we obtain the \text{MSE}

\[
\text{MSE} = \mathcal{E} (\|x - \hat{x}\|^2) = \frac{\Delta^2}{12} \sum_{j=1}^N \lambda_j^{-1}.
\]

To study the asymptotic behavior of the error components, we study as \( \Delta \to 0^+ \) the normalized quantization error

\[
\frac{1}{\Delta} (x - \hat{x}) = \sum_{j=1}^N \frac{1}{\Delta} \tau_\Delta (x \cdot v_j) u_j.
\] (4.4)
Theorem 4.4 Let $X \in \mathbb{R}^d$ be an absolutely continuous random vector. Let $\{w_j\}_{j=1}^m$ be a collection of linearly independent vectors in $\mathbb{R}^d$. Then

$$\left[ \frac{1}{\Delta} \tau \Delta (X \cdot w_1), \ldots, \frac{1}{\Delta} \tau \Delta (X \cdot w_m) \right]^T$$

converges in distribution as $\Delta \to 0^+$ to a random vector uniformly distributed in $[-1/2, 1/2]^m$.

Proof. Denote $Y_j = X \cdot w_j$. Since $\{w_j\}$ are linearly independent, $Y = [Y_1, \ldots, Y_m]^T$ is absolutely continuous with some joint density $f(x)$, $x \in \mathbb{R}^m$. As a consequence of (4.2) one has that the distribution of $Z = [Z_1, \ldots, Z_m]^T$, where $Z_j = \frac{1}{\Delta} \tau \Delta (Y_j) = \left\{ \frac{Y_j}{\Delta} + \frac{1}{2} \right\} - \frac{1}{2}$, is

$$f_{\Delta}(x) := \Delta^m \sum_{a \in \mathbb{Z}^m} f(\Delta x - \Delta a).$$

(4.5)

for $x \in [-1/2, 1/2]^m$. Again denote $I_1 := [-1/2, 1/2]$. It is easy to see that $\|f_{\Delta}\|_{L^1(I_1^m)} \leq \|f\|_{L^1(\mathbb{R}^m)}$, for

$$\|f_{\Delta}\|_{L^1(I_1^m)} = \int_{I_1^m} |f_{\Delta}(x)| \, dx$$

$$\leq \sum_{a \in \mathbb{Z}^m} \int_{I_1^m} \Delta^m |f(\Delta x - \Delta a)| \, dx$$

$$= \sum_{a \in \mathbb{Z}^m} \int_{\Delta I_1^m + \Delta a} |f(y)| \, dy$$

$$= \int_{\mathbb{R}^m} |f(y)| \, dy$$

$$= \|f\|_{L^1(\mathbb{R}^m)}.$$

Now, if $\Omega = [a_1, b_1] \times \cdots \times [a_m, b_m]$ and $f(x) = 1_{\Omega}(x)$, then for $x \in I_1^m$ observe that $f_{\Delta}(x) = \Delta^m K_{\Delta}$ where $K_{\Delta}(x) = \# \{a \in \mathbb{Z}^m : \Delta x + \Delta a \in \Omega \}$. Obviously, $K_{\Delta}(x) = s/\Delta^m + O(\Delta^{-m+1})$ where $s = \mathcal{L}(\Omega)$ is the Lebesgue measure of $\Omega$. Then $f_{\Delta} \to s I_1^m$ in $L^1(I_1^m)$ as $\Delta \to 0^+$.

Coming back to the case when $f(x)$ is the density of $Y$. For any $\varepsilon > 0$ it is possible to choose a $g(x) \in L^1(\mathbb{R}^m)$ such that $\|f - g\|_{L^1} < \frac{\varepsilon}{3}$, and furthermore,
\[ g(x) = \sum_{j=1}^{N} c_j 1_{E_j}(x) \] is a simple function where \( c_j \in \mathbb{R} \) and each \( E_j \) is a product of finite intervals.\footnote{Remark: We in fact proved a slightly stronger result, namely the densities converge in \( L^1 \). Applying the above theorem to the MSE, if \( \{v_j\}_{j=1}^{N} \) are pairwise linearly independent then the error components \( \{\tau_{\Delta} (X \cdot v_j)\}_{j=1}^{N} \) become asymptotically pairwise independent and each uniformly distributed in \([-\Delta^2, \Delta^2]\).}

Observe that \( \int_{\mathbb{R}^m} g = \sum_{j=1}^{N} c_j \mathcal{L}(E_j) \). Since \( (1_{E_j})_\Delta \to \mathcal{L}(E_j) 1_{I_1^m} \) in \( L^1 \) we have \( g_\Delta \to (\int_{\mathbb{R}^m} g) 1_{I_1^m} \) as \( \Delta \to 0 \). Hence there exists a \( \delta > 0 \) such that
\[
\|g_\Delta - (\int_{\mathbb{R}^m} g) 1_{I_1^m}\|_{L^1} < \varepsilon /3 \quad \text{whenever} \quad \Delta < \delta.
\]

Now, for \( \Delta < \delta \),
\[
\|f_\Delta - 1_{I_1^m}\|_{L^1(I_1^m)} = \|f_\Delta - g_\Delta\|_{L^1(I_1^m)} + \|g_\Delta - (\int_{\mathbb{R}^m} g) 1_{I_1^m}\|_{L^1(I_1^m)} + 1 - (\int_{\mathbb{R}^m} g)\|1_{I_1^m}\|_{L^1(I_1^m)}
\]
\[
< \frac{\varepsilon}{3} + \frac{\varepsilon}{3} + |1 - (\int_{\mathbb{R}^m} g)|
\]
\[
= \frac{2\varepsilon}{3} + |(\int_{\mathbb{R}^m} g) - (\int_{\mathbb{R}^m} g)|
\]
\[
< \varepsilon.
\]

\[\blacksquare\]

Corollary 4.5 Let \( X \in \mathbb{R}^d \) be an absolutely continuous random vector. If \( \{v_j\}_{j=1}^{N} \) are pairwise linearly independent, then as \( \Delta \to 0^+ \) we have
\[
\mathcal{E}(\|X - \bar{X}\|_2^2) = \frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1} + o(\Delta^2) = \frac{\Delta^2}{12} \sum_{j=1}^{N} \|u_j\|^2 + o(\Delta^2).
\]
and \( \mathcal{E}(Z_iZ_j) \to \frac{1}{12}\delta_{ij} \) as \( \Delta \to 0^+ \). It follows from the proof of Proposition 3.2 that

\[
\frac{1}{\Delta^2} \mathcal{E}(\|X - \tilde{X}\|^2) = \mathcal{E}(Z^THZ)
\]

\[
= \mathcal{E} \left( \sum_{i,j=1}^{N} Z_iZ_j h_{ij} \right)
\]

\[
= \sum_{i,j=1}^{N} h_{ij} \mathcal{E}(Z_iZ_j)
\]

\[
= \frac{1}{12} \sum_{i=1}^{N} h_{ii} + o(1)
\]

\[
= \frac{1}{12} \sum_{j=1}^{d} \lambda_j^{-1} + o(1),
\]

and hence

\[
\mathcal{E}(\|X - \tilde{X}\|^2) = \frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1} + o(\Delta^2) = \frac{\Delta^2}{12} \sum_{j=1}^{N} \|u_j\|^2 + o(\Delta^2).
\]

\[
4.3 \text{ Asymptotic Behavior of Errors: Linear Dependence Case}
\]

In this section we consider the case in which some vectors in the frame may be parallel. This can happen, for example, if the frame contains redundant elements. Mathematically it would be interesting to understand how the MSE behaves as \( \Delta \to 0^+ \). We return to previous calculations and note that

\[
\mathcal{E}(\|X - \tilde{X}\|^2) = \sum_{i,j=1}^{N} h_{ij} \mathcal{E}(\tau_\Delta(X \cdot v_i)\tau_\Delta(X \cdot v_j)).
\]

Our main result in this section is:

**Theorem 4.6** Let \( X \) be an absolutely continuous real random variable. Let \( \alpha \in \)
\( \mathbb{R} \setminus \{0\} \). Then

\[
\lim_{\Delta \to 0^+} \frac{1}{\Delta^2} \mathcal{E}(\tau_\Delta(X) \tau_\Delta(\alpha X)) = \begin{cases} 
0, & \alpha \notin \mathbb{Q}, \\
\frac{1}{12pq}, & \alpha = \frac{p}{q} \text{ and } p + q \text{ is even,} \\
-\frac{1}{24pq}, & \alpha = \frac{p}{q} \text{ and } p + q \text{ is odd},
\end{cases}
\tag{4.7}
\]

where \( p, q \) are coprime integers.

**Proof.** Denote \( g(x) := \{ x + \frac{1}{2} \} - \frac{1}{2} \). Let \( \phi(x) \geq 0 \) be an even \( C^\infty \) function such that \( \text{supp}(g) \subseteq [-1, 1] \) and \( \int_{\mathbb{R}} \phi = 1 \). Let \( g_n(x) = g \ast \phi_n \) where \( \phi_n(x) = n\phi(nx) \). It is standard to check that

(a) \( |g_n(x)| \leq 1/2 \);

(b) \( \text{supp}(g(x) - g_n(x)) \subseteq [\frac{1}{2} - \frac{1}{n}, \frac{1}{2} + \frac{1}{n}] + \mathbb{Z} \);

(c) \( g_n(x) \in C^\infty \), and is \( \mathbb{Z} \)-periodic;

(d) \( \int_{\mathbb{R}} g_n(x) \, dx = 0 \).

\( g_n(x) \) represents a small perturbation of \( g(x) \) that “smoothes out” the discontinuities of \( g(x) \). Now, set

\[
E(\Delta) := \mathcal{E} \left( \frac{1}{\Delta^2} \tau_\Delta(X) \tau_\Delta(\alpha X) \right)
\]

\[
= \mathcal{E} \left( g \left( \frac{X}{\Delta} \right) g \left( \frac{\alpha X}{\Delta} \right) \right)
\]

\[
= \int_{\mathbb{R}} g \left( \frac{x}{\Delta} \right) g \left( \frac{\alpha x}{\Delta} \right) f(x) \, dx,
\]

and

\[
E_n(\Delta) := \int_{\mathbb{R}} g_n \left( \frac{x}{\Delta} \right) g_n \left( \frac{\alpha x}{\Delta} \right) f(x) \, dx.
\]

**Claim:** \( E_n(\Delta) \to E(\Delta) \) as \( n \to \infty \) uniformly for all \( \Delta > 0 \).
Proof of the Claim. Let $f$ be the density of $X$. For any $\varepsilon > 0$,

$$|E_n(\Delta) - E(\Delta)| = \left| \int_{\mathbb{R}} \left[ g_n \left( \frac{x}{\Delta} \right) g_n \left( \frac{\alpha x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) g \left( \frac{\alpha x}{\Delta} \right) \right] f(x) \, dx \right|$$

$$\leq \frac{1}{2} \int_{\mathbb{R}} \left| g_n \left( \frac{x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) \right| f(x) \, dx + \frac{1}{2} \int_{\mathbb{R}} \left| g_n \left( \frac{\alpha x}{\Delta} \right) - g \left( \frac{\alpha x}{\Delta} \right) \right| f(x) \, dx.$$

Now there exists an $M > 0$ such that $\int_{[-M,M]} f(x) \, dx < \frac{\varepsilon}{2}$. So

$$\int_{\mathbb{R}} \left| g_n \left( \frac{x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) \right| f(x) \, dx \leq \int_{-M}^{M} \left| g_n \left( \frac{x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) \right| f(x) \, dx + \frac{\varepsilon}{2}.$$

Furthermore, let $A_n(\Delta, M) := \text{supp}(g_n(x/\Delta) - g(x/\Delta)) \cap [-M, M]$. Then we have

$$A_n(\Delta, M) \subseteq \Delta \left( \left[ \frac{1}{2} - \frac{1}{n} ; \frac{1}{2} + \frac{1}{n} \right] + \mathbb{Z} \right) \cap [-M, M].$$

Hence $\mathcal{L}(A_n(\Delta, M)) \leq \frac{2M \cdot 2\Delta}{n} = \frac{4M}{n}$, and thus

$$\int_{-M}^{M} \left| g_n \left( \frac{x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) \right| f(x) \, dx \leq \int_{A_n(\Delta, M)} f(x) \, dx < \frac{\varepsilon}{2},$$

by choosing $n$ sufficiently large (independent of $\Delta$), which yields

$$\int_{\mathbb{R}} \left| g_n \left( \frac{x}{\Delta} \right) - g \left( \frac{x}{\Delta} \right) \right| f(x) \, dx < \varepsilon.$$

Similarly we have

$$\int_{\mathbb{R}} \left| g_n \left( \frac{\alpha x}{\Delta} \right) - g \left( \frac{\alpha x}{\Delta} \right) \right| f(x) \, dx < \varepsilon$$

for sufficiently large $n$, proving the Claim. \hfill \square

Now consider the Fourier Series of $g_n(t)$,

$$g_n(t) = \sum_{k \in \mathbb{Z}} c_k^{(n)} e^{2\pi i k t}.$$

It is well known that the Fourier series converges to $g_n(t)$ uniformly for all $t$, see e.g. [45]. Furthermore, since $g_n(t)$ is $C^\infty$ we have $|c_k^{(n)}| = o \left( (|k| + 1)^{-L} \right)$ for all $L > 0$, giving absolute convergence of the Fourier series. Thus

$$E_n(\Delta) = \lim_{K \to \infty} \int_{\mathbb{R}} \left( \sum_{|k| \leq K} c_k^{(n)} e^{2\pi i k t} \Delta^{-1} \right) \left( \sum_{|\ell| \leq K} c_{\ell}^{(n)} e^{2\pi i \alpha \ell} \Delta^{-1} \right) f(t) \, dt$$

$$= \lim_{K \to \infty} \sum_{|k|, |\ell| \leq K} c_k^{(n)} c_{\ell}^{(n)} \overline{f} \left( -\frac{k + \alpha \ell}{\Delta} \right).$$
Observe that $|\hat{f}(\xi)| \leq \|f\|_{L^1} = 1$, and $|c_k^{(n)}| = o\left((|k| + 1)^{-L}\right)$ for any $L > 0$. So the series converges absolutely and uniformly in $\Delta$. Thus

$$E_n(\Delta) = \sum_{k,\ell \in \mathbb{Z}} c_k^{(n)} c_{\ell}^{(n)} \hat{f}\left(-\frac{k + \alpha \ell}{\Delta}\right). \quad (4.8)$$

For any $n > 0$ we have

$$\lim_{\Delta \to 0^+} E_n(\Delta) = \sum_{k,\ell \in \mathbb{Z}} c_k^{(n)} c_{\ell}^{(n)} \lim_{\Delta \to 0^+} \hat{f}\left(-\frac{k + \alpha \ell}{\Delta}\right)$$

because the series converges absolutely and uniformly. Suppose $\alpha \notin \mathbb{Q}$. Then $k + \alpha \ell \neq 0$ if either $k \neq 0$ or $\ell \neq 0$. Thus $\left|-\frac{k + \alpha \ell}{\Delta}\right| \to \infty$, and hence $\lim_{\Delta \to 0^+} \hat{f}\left(-\frac{k + \alpha \ell}{\Delta}\right) = 0$ as $f \in L^1(\mathbb{R})$. Note also that $c_0^{(n)} = \int_{\mathbb{R}} g_n = 0$. It follows that

$$\lim_{\Delta \to 0^+} E_n(\Delta) = 0.$$

But $E_n(\Delta) \to E(\Delta)$ as $n \to \infty$ uniformly in $\Delta$, which yields $E(\Delta) \to 0$ as $\Delta \to 0^+$.

Next, suppose $\alpha = \frac{p}{q}$ where $p, q \in \mathbb{Z}$, $(p, q) = 1$. We observe that $k + \alpha \ell = 0$ if and only if $k = pm$ and $\ell = -qm$ for some $m \in \mathbb{Z}$. In such a case

$$\hat{f}\left(-\frac{k + \alpha \ell}{\Delta}\right) = \hat{f}(0) = \int_{\mathbb{R}} f = 1.$$

It follows that

$$\lim_{\Delta \to 0^+} E_n(\Delta) = \sum_{m \in \mathbb{Z}} c_m^{(n)} c_{-qm}^{(n)} \hat{f}(0) = \sum_{m \in \mathbb{Z}} c_m^{(n)} c_{-qm}^{(n)} = \sum_{m \in \mathbb{Z}} c_m^{(n)} c_{qm}^{(n)}.$$

For $r \in \mathbb{Z}, r \neq 0$ set

$$G_r^{(n)}(x) := \sum_{m \in \mathbb{Z}} c_m^{(n)} e^{2\pi imx}.$$

By Parseval we have

$$\lim_{\Delta \to 0} E_n(\Delta) = \langle G_q^{(n)}, G_p^{(n)} \rangle_{L^2([0,1])}.$$

It is easy to check that

$$G_r^{(n)} = \frac{1}{|r|} \sum_{j=0}^{|r|-1} g_n\left(\frac{x + j}{r}\right).$$
Hence $G_r^{(n)}$ converges in $L^2([0,1])$ to $G_r(x) := \frac{1}{|r|} \sum_{j=0}^{\lfloor |r|/2 \rfloor} g(\frac{x+j}{r})$, which has Fourier series $G_r(x) = \sum_{m \in \mathbb{Z}} c_{rm} e^{2\pi i m x}$ with $c_0 = 0$ and $c_k = \frac{(-1)^{k-1}}{2\pi i k}$ for $k \neq 0$. This yields

$$\lim_{n \to \infty} \lim_{\Delta \to 0^+} E_n(\Delta) = \lim_{n \to \infty} \langle G_q^{(n)}, G_p^{(n)} \rangle = \langle G_q, G_p \rangle = \sum_{m \in \mathbb{Z}} c_{qm} c_{pm}.$$ 

Finally

$$\sum_{m \in \mathbb{Z}} c_{qm} c_{pm} = \sum_{m \in \mathbb{Z} \setminus \{0\}} \frac{(-1)^{qm-1}}{2\pi i m q} \frac{(-1)^{pm-1}}{2\pi i m p} = \frac{1}{2pq \pi^2} \sum_{m=1}^{\infty} \frac{(-1)^{p+q} m}{m^2}.$$

Note that if $p+q$ is even then \(\sum_{m=1}^{\infty} \frac{(-1)^{p+q} m}{m^2} = \sum_{m=1}^{\infty} \frac{1}{m^2} = \frac{\pi^2}{6}\). On the other hand, if $p+q$ is odd then \(\sum_{m=1}^{\infty} \frac{(-1)^{p+q} m}{m^2} = \sum_{m=1}^{\infty} \frac{(-1)^m}{m^2} = -\frac{\pi^2}{12}\). The theorem follows.

\[\blacksquare\]

**Corollary 4.7** Let $X$ be an absolutely continuous random vector in $\mathbb{R}^d$, $w \neq 0$, $w \in \mathbb{R}^d$ and $\alpha \in \mathbb{R} \setminus \{0\}$. Then

$$\lim_{\Delta \to 0^+} \frac{1}{\Delta^2} \mathcal{E}(\tau_\Delta(w \cdot X) \tau_\Delta(\alpha w \cdot X)) = \begin{cases} 0, & \alpha \neq Q, \\ \frac{1}{12pq}, & \alpha = \frac{p}{q} \text{ and } p + q \text{ is even}, \\ -\frac{1}{24pq}, & \alpha = \frac{p}{q} \text{ and } p + q \text{ is odd}, \end{cases} \quad (4.9)$$

where $p, q$ are coprime integers.

**Proof.** We only need to note that $w \cdot X$ is an absolutely continuous random variable. The corollary follows immediately from Theorem 4.4.

\[\blacksquare\]

We can now characterize completely the asymptotic behavior of the MSE in all cases. For any two vectors $w_1, w_2 \in \mathbb{R}^d$ define $r(w_1, w_2)$ by

$$r(w_1, w_2) = \begin{cases} \frac{1}{pq} w_1 \cdot w_2, & w_1 = \frac{p}{q} w_2, \text{ and } p + q \text{ is even}, \\ -\frac{1}{2pq} w_1 \cdot w_2, & w_1 = \frac{p}{q} w_2, \text{ and } p + q \text{ is odd}, \\ 0, & \text{otherwise}, \end{cases}$$
where $p, q$ are coprime integers.

**Corollary 4.8** Let $X \in \mathbb{R}^d$ be an absolutely continuous random vector. Then as $\Delta \to 0^+$ the MSE satisfies

$$
\mathcal{E}(\|x - \hat{x}\|^2) = \frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1} + \frac{\Delta^2}{6} \sum_{1 \leq i < j \leq N} r(u_i, u_j) + o(\Delta^2),
$$

(4.10)

**Proof.** In the proof of (4.5) we showed that

$$
\lim_{\Delta \to 0^+} \frac{1}{\Delta^2} \mathcal{E}(\|x - \hat{x}\|^2) = \sum_{i,j} h_{ij} \mathcal{E}(Z_i Z_j)
$$

with the notations there. The result is immediate from Theorem 4.7. ■

For fixed quantization step $\Delta > 0$ we shall denote

$$
\text{MSE}_{\text{ideal}} = \frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1} + \frac{\Delta^2}{6} \sum_{1 \leq i < j \leq N} r(u_i, u_j),
$$

(4.11)

and call it the *ideal MSE*. If $\{v_j\}_{j=1}^{N}$ are pairwise linearly independent, then the MSE$_{\text{ideal}}$ is simply $\frac{\Delta^2}{12} \sum_{j=1}^{d} \lambda_j^{-1}$, the MSE under the WNH.

We should point out that even though the WNH is not true asymptotically if some vectors in a frame are parallel, the contribution from the second part of (4.11) is often small enough that the MSE under the WNH is close enough to the ideal MSE. In Appendix we shall show some numerical data, comparing the actual MSE with the ideal MSE.
PART II

The Analysis of Beta-Alpha Analog-to-Digital Encoders
CHAPTER V

REPRESENTATIONS OF REAL NUMBERS

With the development of writing systems, as well as the growth in the complexity of the trade and engineering experienced by mankind around the 4th millennium BC, the need of numeral systems was as self evident as it is today. The historical development of such concepts is far from the scope of this work. Nevertheless we give a brief introduction to some of the most widely used systems today.

5.1 Decimal and Binary Representations

The decimal representation is without a doubt the most widely used numeral system in every day life around the world. The decimal system is a positional notation numeral system. This means, the symbols 0, 1, 2, 3, 4, 5, 6, 7, 8 and 9 represent respectively the first ten non-negative integer numbers, and are called *digits*, and thus on any given representation of a number, a position is related to the next by the common ratio of 10, that is called the *base* or *radix*. As the reader should be more than familiar, the string 1981 represents $1 \cdot 10^3 + 9 \cdot 10^2 + 8 \cdot 10^1 + 1 \cdot 10^0$ and the string 37.125 represents $3 \cdot 10^1 + 7 \cdot 10^0 + 1 \cdot 10^{-1} + 2 \cdot 10^{-2} + 5 \cdot 10^{-3}$.

The election of 10 as the radix of the system is not arbitrary, as the fingers of our hands were the first counting machines available, but any positive integer other than 1 can be used for such purpose. The first, and in some sense, the “mathematically most natural” choice for such radix would be the number 2, or *binary*. In this case, each number is represented by a finite or infinite string of zeros and ones. In this case, the number that was previously represented as 37.125 in decimal notation, would be represented in binary by 10011.001.

The historical success of positional systems comes from the fact that they ease
the symbolic computation of the basic arithmetic computations, although, in modern Mathematics, there are other systems used. Most of them can be considered as particular cases of \( f \)-expansions for real numbers. These would be introduced in the next section.

5.2 \( f \)-Expansions for Real Numbers

A mathematically interesting way to express real numbers is the use of continued fractions. For example, the number obtained by dividing 59 by 26 can be represented in decimal notation by \( 2.26923076923 \cdots = 2.2692307 \). On the other hand, note that

\[
\frac{59}{26} = 2 + \frac{1}{3 + \frac{1}{1 + \frac{1}{2 + \frac{1}{2}}} }
\]

and thus such number could be represented also by \([2; 3, 1, 2, 2]\).

The representation of numbers through continued fractions has been vastly studied for the last three centuries. In 1944 Bissinger established that these are, together with decimal and binary representation, particular cases of what he called \( f \)-expansions for real numbers (See [5]).

In general term, an \( f \)-expansion scheme yields a representation for a non-negative number \( x \) through the iteration of the function \( y = f(x) \). Define

\[
\begin{align*}
b_0 &= \lfloor x \rfloor \\
x_0 &= x - b_0 \\
b_n &= \lfloor f^{-1}(x_{n-1}) \rfloor \\
x_n &= f^{-1}(x_{n-1}) - b_n
\end{align*}
\]

(5.1)

where \( \lfloor \cdot \rfloor \) represents the integer part. With this information, one should be able to reconstruct \( x \) by

\[
x = b_0 + f(b_1 + f(b_2 + f(b_3 + \cdots ))). \tag{5.2}
\]

There are of course several conditions that \( f \) should satisfy to obtain a valid \( f \)-expansion scheme (See [37]). At the very least, there should be sets \( \mathcal{R} \) and \( \mathcal{D} \), such
that $\mathcal{R} \subseteq [0, 1]$, $\mathcal{D}$ is a subset of the non-negative real numbers and $f : \mathcal{D} \to \mathcal{R}$ is a bijection. Normally, both $\mathcal{D}$ and $\mathcal{R}$ are intervals.

The binary system correspond to $f(x) = x/2$, where $\mathcal{D} = [0, 2)$ and $\mathcal{R} = [0, 1)$. In the case of the continued functions, $f(x) = x^{-1}$, with $\mathcal{D} = [1, \infty)$ and $\mathcal{R} = (0, 1]$ and the additional condition that the iterations should stop the first time that $x_n = 0$ for some $n$.

In Chapter 6 we will analyze the use of binary representation in A/D conversion, as well as the so called $\beta$-expansion (another particular case of $f$-expansions), their strenghts and potential weaknesses. In Chapter 7 we will introduce the $\beta\alpha$-expansions, a variation of $\beta$-expansions that overcomes some of limitations of the latter. Finally, in Chapter 8 we will analyze some of the ergodic properties of the dynamical system introduced by the $\beta\alpha$-expasions.
CHAPTER VI

THE $\beta$-ENCODER

The constant need to improve current strategies and technologies to encode images, video or audio in order to obtain a better quality with a lesser cost on the existing resources makes analog-to-digital (A/D) conversion a dynamic area of research.

One of the most basic problems within this area consist in the representation of a signal $x$ coming from a continuous media using a string of characters coming from a finite alphabet, a digital expression.

6.1 Imperfect Quantizers

Probably the better known scheme to obtain a digital expresion of a signal is using a binary expansion. On this scheme, a finite or infinite string of binary digits is obtained to represent $x \in [0, 1)$ in the following way

$$
\begin{align*}
x_0 &= x \\
b_n &= Q(2x_{n-1}) \\
x_n &= 2x_{n-1} - b_n
\end{align*}
$$

where the quantization function $Q$ is given by

$$
Q(t) = \begin{cases} 
0 & \text{if } t < 1, \\
1 & \text{otherwise.}
\end{cases}
$$

(6.2)

This leads to a perfect reconstruction method given by

$$
x = \sum_{n=1}^{\infty} b_n 2^{-n}.
$$

(6.3)

Furthermore the accuracy improves exponentially as more bits are used.

$$
\left| x - \sum_{n=1}^{N} b_n 2^{-n} \right| < 2^{-N}.
$$
One important drawback on this scheme is the fact that such representation is unique for almost all $x$, in the sense that if $\{b_n\}$ is the binary representation of $x$ and $b_{n_k} \neq \tilde{b}_{n_k}$ for a collection $\{n_k\}_k$, then

$$\sum_{n=1}^{\infty} b_n 2^{-n} \neq \sum_{n=1}^{\infty} \tilde{b}_n 2^{-n}.$$  

The importance of such drawback comes from the fact that in a practical implementation, the scheme has a quantization threshold. In a practical setup, the quantizer given in (6.2) is unattainable with infinite precision, and instead the available quantizer $Q_f$ has some indetermination

$$Q_f(t) = \begin{cases} 
0 & \text{if } t < \nu_1, \\
0 \text{ or } 1 & \text{if } \nu_1 \leq t \leq \nu_2, \\
1 & \text{otherwise},
\end{cases} \quad (6.4)$$

where the values of $\nu_1$ and $\nu_2$ are unknown, though, they lie within a known range. If the source of the signal is assumed to be uniformly distributed in $[0, 1]$, and $\nu_1 < \nu_2$, then the scheme would fail to produce a correct encoding with probability 1. Furthermore, if during the encoding, a quantization error is made on the $n$-th iteration, then, the reconstruction error is at least $2^{-n} |x_n - \frac{1}{2}|$.

The $\beta$-quantization scheme was recently introduced in [10] and studied in more detail in [12] and [13]. Here we introduce a variant of the $\beta$-expansion quantization scheme, where the introduction of a secondary parameter $\alpha$ improves the robustness of the scheme without sacrificing the exponential accuracy reached by it.

### 6.2 $\beta$-Expansions

The so-called $\beta$-encoder is based on the $\beta$-expansion introduced originally in [37] as a particular case of an $f$-expansion. There, Renyi introduced the possibility to use non-integral bases to represent real numbers. Then, given a non integer $\beta > 1$, if
0 < x < 1 one can express any 0 ≤ x ≤ 1 as

\[ x = \sum_{n=1}^{\infty} b_n \beta^{-n}. \]  \hspace{1cm} (6.5)

The digits \( b_n \) can be chosen recursively by

\[
\begin{align*}
x_0 & = x \\
b_n & = \lfloor \beta x_{n-1} \rfloor \\
x_n & = \beta x_{n-1} - b_n
\end{align*}
\]  \hspace{1cm} (6.6)

where \( \lfloor \cdot \rfloor \) denotes the integer part. At each step, \( 0 \leq b_i \leq \lfloor \beta \rfloor \). There is an immediate gain using this representation instead of the representation obtained by an integral base: There are many possible choices of \( \{b_n\} \) that still yield a valid reconstruction for \( x \) with the expansion (6.5). In fact it is proved (see Sidrov [39]) that for almost every \( x \in (0, 1) \) there are uncountably many such representations.

Furthermore, in [34], Parry proved the following theorem.

**Theorem 6.1** Let \( 1 < \beta \) and let \( T(x) = \beta x \mod 1 \). Consider the function

\[ h(x) = \sum_{x<T^n(1)} \frac{1}{\beta^n}, \]

where \( T^0(1) = 1 \), and consider the measure \( \nu \) on \([0, 1]\) given by

\[ \nu(E) = \int_E h(x)d\mu \]

Then \( \nu \) is a finite positive \( T \)-invariant measure that is ergodic with respect to \( T \).

Note that if \( \{x_n\}_{n \geq 0} \) are defined as in (6.6), and \( T \) as in the theorem above, then \( x_{n+1} = T(x_n) \). This function, often denoted as \( T_\beta \), is generally called the \( \beta \)-transformation, and it has been widely studied by Renyi [37], Parry [34, 35], Kopf [27] among others.
6.3 Robustness of the $\beta$-Encoder

Even with the vast literature on the $\beta$-transformation dating back to the late 1950s, to the best of the knowledge of the author, it was not until 2002 when Daubechies, DeVore, Güntürk and Vaishampayan saw the advantages it could offer for A/D conversion (See [10, 12]). They introduced the idea of a $\beta$-encoder, which enables one to overcome the imprecision of the quantizers, i.e. the flaky quantizer problem, by introducing redundancy in the representation of the signal.

Using the non-uniqueness (redundancy) of $\beta$-expansions, they showed that it is possible to implement a quantizer with an unknown and possibly fluctuating threshold (although a such threshold has to be contained within a certain range) that would yield a perfect reconstruction of the original input $x$. The following theorem is proved in [12]:

**Theorem 6.2** Let $1 < \beta < 2$, $0 \leq x < 1$, $1 \leq \nu_0 < \nu_1 \leq (\beta - 1)^{-1}$ and $Q_f$ as defined in (6.4), and define $x_f^0$, $b_f^n$ by the algorithm

\[
\begin{align*}
    x_f^0 &= x, \\
    b_f^n &= Q_f(\beta x_f^{n-1}), \\
    x_f^n &= \beta x_f^{n-1} - b_f^n.
\end{align*}
\]

(6.7)

Then, for all $N \in \mathbb{N}$

\[
0 \leq x - \sum_{n=1}^{N} b_f^n \beta^{-n} \leq \nu_1 \beta^{-N}.
\]

Note that $\nu_1 \geq 1$. This means that even though the $\beta$-encoder allows certain imprecision on the quantizer, it does not allow the quantizer to err upward, i.e. reading off a 0 as a 1. The scheme would fail if this occurs. In Figure 1 one can appreciate how the ranges where $b_n = 0$ and $b_n = 1$ intersect, but if $x_n < 1$, then the scheme fails if one obtains an output $b_n = 1$.

To overcome this problem we consider an alternative. We introduce the $\beta\alpha$ encoder as a variation of the $\beta$-encoder, which allows for precise reconstruction in the case of
Figure 1: Shown in the image, the ranges for $x_n$ producing respectively $b_n = 0$ and $b_n = 1$ for $\beta = 5/3$, where a stable reconstruction is possible.

$\nu_1 < 1$. 
CHAPTER VII

$\beta\alpha$-ENCODER

As it has been already discussed, a $\beta$-expansion of a real number $x \in [0, 1]$ is any collection of digits $\{b_n\}_{n \in \mathbb{N}}$ such that

$$x = \sum_{n \in \mathbb{N}} b_n \beta^{-n}.$$

Such expression is far from unique. A very intuitive way to obtain such a collection of digits is described by (6.6), and thus we will call this specific $\beta$-expansion of $x$ as its canonical expansion. In this chapter we will analyze another way to obtain $\beta$-expansions, and will seize on the properties of this alternative method to obtain a stable scalar quantization scheme where the implementation can be given with some freedom unattained by the $\beta$-Encoder.

7.1 A Non-Canonical $\beta$-Expansion

We will introduce a non-canonical $\beta$-expansion, that we will call a $\beta\alpha$-expansion. This one is similar to the $\beta$-expansion in that it still uses a possibly non-integer $\beta$ as the base. However, unlike in the $\beta$-expansion the digits $b_n$ are obtained at each stage using an amplification factor $\alpha$ instead of $\beta$. More precisely, for any $0 \leq x < 1$ we set $x_0 = x$ and obtain $b_n$, $x_n$ for $n \geq 1$ using the following scheme:

$$b_n = \lfloor \alpha x_{n-1} \rfloor,$$

$$x_n = \beta x_{n-1} - b_n.$$  \hspace{1cm} (7.1)

Observe that $x_{n-1} = \beta^{-1}(x_n + b_n)$ for every $n \geq 1$, and therefore, nesting this identity we obtain for any $N \in \mathbb{N}$ the expression

$$x = \beta^{-N} x_N + \sum_{n=1}^{N} b_n \beta^{-n},$$
or equivalently,

\[ x - \sum_{n=1}^{N} b_n \beta^{-n} = \beta^{-N} x_N. \tag{7.2} \]

In order for perfect reconstruction \( x = \sum_{n=1}^{\infty} b_n \beta^{-n} \) we will need \( \beta^{-N} x_N \to 0 \), preferably at an exponential rate. To make it happen, let \( \{t\} \) denote the fractional part of \( t \). Then \( x = \lfloor x \rfloor + \{x\} \), and

\[
\begin{align*}
x_N &= \beta x_{N-1} - b_N \\
&= \beta x_{N-1} - \lfloor \alpha x_{N-1} \rfloor \\
&= \beta x_{N-1} - \alpha x_{N-1} + \{\alpha x_{N-1}\} \\
&= (\beta - \alpha) x_{N-1} + \{\alpha x_{N-1}\} \\
&= (\beta - \alpha)^N x + \sum_{n=1}^{N} \{\alpha x_{n-1}\}.
\end{align*}
\]

Since \( 0 \leq \{t\} < 1 \), it follows that \((\beta - \alpha)^N x \leq x_N < (\beta - \alpha)^N x + N\), and

\[
\beta^{-N}(\beta - \alpha)^N x \leq \beta^{-N} x_N < \beta^{-N}((\beta - \alpha)^N x + N).
\]

Thus if we set \( \beta > 1 \) and \( 0 < \alpha \leq \beta \) we will ensure a perfect reconstruction with exponential rate convergence. Furthermore, all \( x_n \geq 0 \) and hence all digits \( b_n \) are nonnegative. For quantization applications, the magnitude of \( x_n \) matters because it determines the magnitude of \( b_n \). Since these digits \( b_n \) must come from a finite alphabet we shall require that \( x_n \) be bounded. A necessary condition is \( \beta - \alpha < 1 \).

In what follows we focus on the case \( 0 \leq \beta - \alpha < 1 \). We ask the following questions: Are \( \{b_n\} \) bounded, and if so, what is the upper bound?

**Lemma 7.1** Let \( 1 < \beta, \alpha \leq \beta \) and \( \beta - \alpha < 1 \). Define \( T(x) = \beta x - \lfloor \alpha x \rfloor \) and set \( \omega = [1 - (\beta - \alpha)]^{-1} \). Let \( K = [\omega(\beta - 1)] \) where \([y]\) denotes the least integer greater than or equal to \( y \). Then the fixed points of \( T \) are \( \{k(\beta - 1)^{-1} : 0 \leq k < K\} \).

**Proof.** First we notice that \( T(x) \geq (\beta - \alpha)x \) implies that \( T(x) > x \) if \( x < 0 \). So \( T \) cannot have a negative fixed point. Now, notice that if \( T(x) = x \) then \( \beta x - k = x \)
where \( k = \lfloor \alpha x \rfloor \). Thus \( x = k(\beta - 1)^{-1} \). So all fixed points must be in the form of \( x = k(\beta - 1)^{-1} \) for some integer \( k \geq 0 \). We shall determine which of these \( k \)'s actually yield fixed points. To do so, let \( x = k(\beta - 1)^{-1} \) be a fixed point. Then \( \beta x - \lfloor \alpha x \rfloor = x \).

It follows that \( \lfloor \alpha x \rfloor = (\beta - 1)x = k \).

Now \( \lfloor \alpha x \rfloor = \alpha x - \{\alpha x\} \). So we have \( \alpha x - k = \{\alpha x\} \). Note that

\[
\alpha x - k = \frac{\alpha k}{\beta - 1} - k = \frac{(1 - \beta + \alpha)k}{\beta - 1} = \frac{k}{\omega(\beta - 1)}.
\]

Thus we have \( k[\omega(\beta - 1)]^{-1} = \{\alpha x\} < 1 \), which yields \( k < \omega(\beta - 1) \) or equivalently, \( k < K \). Conversely, if \( 0 \leq k < K \) and \( x = \frac{k}{\beta - 1} \) the above calculations can be reversed to show that \( x \) is a fixed point.

\[\blacksquare\]

**Proposition 7.2** Let \( 1 < \alpha \leq \beta \) and \( \beta - \alpha < 1 \). Define \( T(x) = \beta x - \lfloor \alpha x \rfloor \) and set

\[
M = \left\lceil \frac{\alpha(\beta - 1)}{\beta[1 - (\beta - \alpha)]} \right\rceil, \tag{7.3}
\]

where \([t]\) denotes the least integer greater than or equal to \( t \). Set \( \tau = M(\beta \alpha^{-1} - 1) + 1 \).

For any \( 0 \leq x \leq \tau \) we have \( 0 \leq T^n(x) < \tau \) for all \( n \geq 1 \).

**Proof.** Note that \( T(x) = (\beta - \alpha)x + \{\alpha x\} \) we have \( T(x) \geq 0 \) for \( x \geq 0 \). Furthermore, as \( \alpha < \beta \), then, \( \alpha(\beta - 1)\omega(\beta - 1) < \omega(\beta - 1) \), where \( \omega = [1 - (\beta - \alpha)]^{-1} \), thus \( M \leq [\omega(\beta - 1)] \). Hence \( (M - 1)(\beta - 1)^{-1} \) is a fixed point. First, for \( x < M\alpha^{-1} \),

\[
T(x) < (\beta - \alpha)x + 1 < (\beta - \alpha)M\alpha^{-1} + 1 = \tau.
\]

If \( M < [\omega(\beta - 1)] \), then, by Lemma 7.1, \( M(\beta - 1)^{-1} \) would be also a fixed point, besides

\[
\frac{\alpha(\beta - 1)}{\beta[1 - (\beta - \alpha)]} < M \Rightarrow M(\beta \alpha^{-1} - 1) + 1 \leq \frac{M}{\beta - 1}
\]

and therefore, for every \( x \in [M\alpha^{-1}, \tau) \), \( T(x) \leq x \), thus \( T(x) < \tau \).

If \( M = [\omega(\beta - 1)] \), then, \((M - 1)(\beta - 1)^{-1} \) is the largest fixed point of \( T \), and thus, for every \( x > M\alpha^{-1} \), \( T(x) < x \).
As it was just proven, $0 \leq x \leq \tau$ implies $0 \leq T(x) \leq \tau$. The iteration step is trivial.

\textbf{Proposition 7.3} Let $1 < \alpha \leq \beta$ and $\beta - \alpha < 1$. Set $M$ and $\tau$ as in Proposition 7.2. For any $x \in [0, \tau)$ define $x_0 = x$ and $x_n, b_n$ for $n \geq 1$ by $b_n = \lfloor \alpha x_{n-1} \rfloor$ and $x_n = x_{n-1} - b_n$. Then $0 \leq x_n < \tau$ and $b_n \in \{0, 1, \ldots, M\}$.

\textbf{Proof.} Notice that $x_n = T^n(x_0)$. By Proposition 7.2 we have $0 < x_n < \tau$. Also, $b_n = \lfloor \alpha x_{n-1} \rfloor$, then, it is enough to prove that $\tau \alpha \leq M + 1$. Now, as $\alpha < \beta$, then $\alpha(\beta - 1) > \beta(\alpha - 1)$, and thus

$$\frac{\alpha - 1}{1 - (\beta - \alpha)} < \frac{\alpha(\beta - 1)}{\beta[1 - (\beta - \alpha)]} \leq M,$$

hence $\alpha - 1 < M[1 - (\beta - \alpha)] \Rightarrow \tau = M(\beta - \alpha) + \alpha < (M + 1)\alpha^{-1} \Rightarrow b_n \leq M$.

We shall point out that the map $T$ is a piece-wise linear so the dynamical system given by $T$ has an invariant measure, see Lasota and York [28] (see also [29]). However there are a few questions that remain to be answered. For example, what are the invariant sets, and what more can we say about the invariant measures? These are interesting mathematical questions that are relevant to the theme of this study. The invariant sets will determine the number of digits in the quantization schemes. It is possible that fewer digits than what we have shown here will be enough. The next question we face is how robust is this scheme, that is, how tolerant is such a scheme to quantizer imperfections. This question will be answered in the next section.

\textbf{7.2 The $\beta\alpha$-Encoder vs. the $\beta$-Encoder}

The $\beta\alpha$-expansion described in the previous section leads naturally to a quantization scheme assuming a perfect quantizer. When a flaky quantizer is used, it can still yield a perfect reconstruction with suitable choices of the parameters.
Bounding ourselves to the conditions $1 < \alpha \leq \beta$, $\beta - \alpha < 1$ and the quantization scheme $x_0 = x$, $b_n = Q_f(\alpha x_{n-1})$ and $x_n = \beta x_{n-1} - b_n$ where set of all possible outputs of $Q_f$ is $\{0, 1, \ldots, B - 1\}$ for some integer $D$, our main concern is to keep $x_N$ bounded for every $N$.

A first natural question is: what bounds should $x_N$ have to preserve a robust scheme? Note that if $x_0 < 0$, then, $x_1 = \beta x_0 - Q_f(\alpha x_0) \leq \beta x_0$, and thus $x_N \leq \beta^{-N} x_0$, making the sequence diverge to negative infinity. From here that $x_n$ should be positive.

On the other hand, note that if $x_N$ is bounded for all $N$, then, by (7.2), one has that

$$x_N = \lim_{K \to \infty} \sum_{n=1}^{K} b_{N+n} \beta^{-n} \leq \sum_{n=1}^{\infty} (B - 1) \beta^{-n} = \frac{B - 1}{\beta - 1}$$

and thus, $x_N \leq (B - 1)(\beta - 1)^{-1}$ for all $N$. We prove the following theorem.

**Theorem 7.4** Let $B$ be a given positive integer, $1 < \beta < B$, $0 \leq x < 1$, $0 < \beta - \alpha < 1$, let $\mu = (B - 1)(\beta - 1)^{-1}$ and let $Q_f$ be defined such that $Q_f(t) \in \{0, 1, \ldots, B - 1\}$, where $Q_f(t) = j \Rightarrow t \in [j\alpha \beta^{-1}, \alpha \beta^{-1}(\mu + j)]$, and define $x^f_n$, $b^f_n$ by the algorithm

$$
\begin{align*}
x^f_0 &= x, \\
b^f_n &= Q_f(\alpha x^f_{n-1}), \\
x^f_n &= \beta x^f_{n-1} - b^f_n.
\end{align*}
$$

(7.4)

Then, for all $n \in \mathbb{N}$, $0 \leq x^f_n \leq \mu$ and

$$0 \leq x - \sum_{n=1}^{N} b^f_n \beta^{-n} \leq \mu \beta^{-N}.$$ 

**Proof.** Note that as $\beta < B$ then $\mu > 1$, and therefore $x^f_0 < \mu$. Note that as $x^f_n = \beta x^f_{n-1} - b^f_n$, then (7.2) is valid regardless of how $b^f_n$ are chosen, therefore it is sufficient to prove that $0 \leq x^f_n \leq \mu$. Let’s now consider the respective subintervals.

Assume that $j \beta^{-1} \leq x^f_n \leq \beta^{-1}(\mu + j)$ and $Q(\alpha x^f_n) = j$, then $0 = \beta(j \beta^{-1}) - j \leq x^f_{n+1} \leq \beta[\beta^{-1}(\mu + j)] - j = \mu$. 

37
Figure 2: Shown in the image, the ranges for $x_n$ producing respectively $b_n = 0$ and $b_n = 1$ for $\beta = 5/3$ and $\alpha = 4/3$, where a stable one-bit reconstruction is possible.

An important remark is that as $\mu > 1$, then $\beta^{-1}(j+1) < \beta^{-1}(\mu+j)$, therefore, the collection of intervals $\{j\beta^{-1}, \beta^{-1}(\mu+j)|0 \leq j \leq B-1\}$ actually covers the interval $[0, \mu]$.

A rephrasing of this theorem for the 1-bit $\beta\alpha$ that resembles Theorem 6.2 would be the following.

**Theorem 7.5** Let $1 < \beta < 2$, $0 \leq x < 1$, $\beta(\beta-1) < \alpha < \beta$, $\alpha\beta^{-1} \leq \nu_0 < \nu_1 \leq \alpha\beta^{-1}(\beta-1)^{-1}$ and $Q_f$ as defined in (6.4), and define $x^f_n$, $b^f_n$ by the algorithm

$$
\begin{align*}
x^f_0 &= x, \\
b^f_n &= Q_f(\alpha x^f_{n-1}), \\
x^f_n &= \beta x^f_{n-1} - b^f_n
\end{align*}
$$

(7.5)

Then, for all $N \in \mathbb{N}$

$$
0 \leq x - \sum_{n=1}^{N} b^f_n \beta^{-n} \leq (\beta - 1)^{-1} \beta^{-N}.
$$

In Figure 2 one can appreciate how the ranges where $b_n = 0$ and $b_n = 1$ intersect, allowing quantizer errors both by excess and by defect, for a one-bit quantization case.
7.3 Imprecise $\alpha$-Multiplication

An imperfect quantizer is not the only problem that can arise in a real application. The multiplication via analog circuits can potentially be another source of inaccuracy. Thus, by performing two multiplications in the $\beta\alpha$-encoder we introduce an extra source for potential errors. In this section, we show that the $\alpha$-multiplication in the $\beta\alpha$-encoder does not have to be very accurate. We prove the following theorem.

**Theorem 7.6** Let $B$ be a given positive integer, $1 < \beta < B$, $0 \leq x < 1$. Let $(\alpha_n)_{n \in \mathbb{N}}$ be a sequence such that

$$\max \left( 0, \frac{\beta \left[ (\beta - 1) - M(1 - c) \right]}{(\beta - 1)(M + 1)} \right) < \beta - \alpha_n \leq c < 1.$$ 

Let $\mu = (B - 1)(\beta - 1)^{-1}$ and let $Q_f$ be defined such that $Q(t) \in \{0, 1, \ldots, M\}$, $Q_f(t) = j \Rightarrow t \in [j(\sup \alpha_k)\beta^{-1}, (\inf \alpha_k)\beta^{-1}(\mu + j)]$ and $Q_f(t) = B - 1$ if $t \geq (\inf \alpha_k)\mu$.

Define $x_n^f$, $b_n^f$ by the algorithm

$$x_0^f = x,$$
$$b_n^f = Q_f(\alpha_n x_{n-1}^f),$$
$$x_n^f = \beta x_{n-1}^f - b_n^f. \quad (7.6)$$

Then, for all $n \in \mathbb{N}$, $0 \leq x_n^f \leq \mu$ and

$$0 \leq x - \sum_{n=1}^{N} b_n^f \beta^{-n} \leq \mu \beta^{-N}.$$ 

**Proof.** Note that trivially, for any integer $n$ and $0 \leq j < B$ one has that

$$[j(\sup \alpha_k)\beta^{-1}, (\inf \alpha_k)\beta^{-1}(\mu + j)] \subseteq [j\alpha_n\beta^{-1}, \alpha_n\beta^{-1}(\mu + j)].$$

Then, the only difference from the proof of Theorem 7.4 is to prove that the set of intervals $I_j = [j(\sup \alpha_k), (\inf \alpha_k)\beta^{-1}(\mu + j)]$ cover $[0, (\inf \alpha_k)\mu\beta]$. As $0 \in I_0$ and $(\inf \alpha_k)\mu \in I_{B-1}$, and as the lower endpoints (as well as the upper endpoints) are in
increasing order, then the only thing left to prove is that \( I_j \cap I_{j+1} \neq \emptyset \). For this, it suffices that \((j + 1) \sup_\alpha k \leq (\mu + j) \inf_\alpha k\), and

\[
\frac{\mu + j}{j + 1} \inf_\alpha k \geq \frac{\mu + (B - 1)}{B} (\beta - c) = \frac{(B - 1)\beta(\beta - c)}{B(\beta - 1)} \geq \sup_\alpha k
\]

by hypothesis.
ERGODIC PROPERTIES OF THE $\beta\alpha$-ENCODER

In the previous chapter we discussed the $\beta\alpha$-Encoder. The scheme defined in (7.1) gives rise to the dynamical system $x_{n+1} = T(x_n)$, where $T(x) = \beta x - \lfloor \alpha x \rfloor$. Beyond its practical applications, this system is tremendously interesting from a mathematical point of view, specifically, the ergodicity of $T$, on which we will focus on this chapter.

8.1 Some Invariant Sets for $T$

We will use the notation introduced in Lemma 7.1, this is, $1 < \beta$, $\alpha \leq \beta$ and $\beta - \alpha < 1$. $T(x) = \beta x - \lfloor \alpha x \rfloor$, $\omega = [1 - (\beta - \alpha)]^{-1}$ and $K = \lceil \omega(\beta - 1) \rceil$ where $[y]$.

For simplicity we will introduce the following additional notation. For $0 < k \leq K$,

$$
\lambda_k = \frac{k}{(\beta - 1)}, \quad \xi_k = k \left( \frac{\beta - \alpha}{\alpha} \right) + 1, \quad \zeta_k = k \left( \frac{\beta - \alpha}{\alpha} \right).
$$

(8.1)

By Lemma 7.1, for $k < K$, $\lambda_k$ are all the fixed points of $T$ other than 0. For $1 \leq k \leq K$, $\xi_k$ the upper extreme of the discontinuity jumps of $T$ as defined in Lemma 7.1, and $\zeta_k$ the lower extremes, for those discontinuities immediately before and immediately after the fixed points.

**Proposition 8.1** If $i$ and $j$ are indices such that $\lambda_{i-1} \leq \zeta_i$ and $\xi_j \leq \lambda_j$, then $\zeta_i < \xi_j$, and $T(x) = \beta x - \lfloor \alpha x \rfloor = (\beta - \alpha)x + \{\alpha x\}$. Consider $\Psi = [\zeta_i, \xi_j]$, then $\Psi$ is invariant, i.e. $T(\Psi) = \Psi$. 

Proof. Note that

\[
\lambda_{i-1} \leq \zeta_i \\
< \zeta_i + 1 - (\beta - \alpha) \\
= \zeta_{i-1} + 1 \\
= \xi_{i-1},
\]

therefore \( j > i - 1 \), i.e. \( i \leq j \), and therefore \( \zeta_i < \xi_j \).

Now, for any \( 0 \leq i \leq n \), \( \zeta_i \leq i\alpha^{-1} < (i+1)\alpha^{-1} < \xi_{i+1} \), and also

\[
T \left( [i\alpha^{-1}, (i+1)\alpha^{-1}] \right) = [\zeta_i, \xi_{i+1}],
\]

therefore, regardless of how \( i \) and \( j \) are chosen, as long as \( 0 \leq i \leq j \leq n \) we would have \( \overline{T(\Psi)} \supseteq \Psi \). Now, as \( \zeta_i < \zeta_{i+1} \) and \( \xi_i < \xi_{i+1} \) for any \( i \), we only have left to prove that for the \( i \) and \( j \) described in the statement, \( T([\zeta_i, i\alpha^{-1}, \xi_j]) \subseteq \Psi \) and \( T([j\alpha^{-1}, \xi_j]) \subseteq \Psi \).

Note that

\[
\sup_{x < i\alpha^{-1}} T(x) = \xi_i \leq \xi_j.
\]

Also, as \( \lambda_{i-1} \leq \zeta_i \leq i\alpha^{-1} \), then, if one takes \( \zeta_i \leq \bar{x} < i\alpha^{-1} \), then \( T(\zeta_i) \leq T(\bar{x}) < \xi_i \).

Note that \( T(x) - x \) is continuous and increasing in such interval, and as \( \lambda_{i-1} \leq \bar{x} \) and \( \lambda_{i-1} \) is a fixed point, one has that \( T(\zeta_i) > \zeta_i \), therefore if \( \zeta_i \leq \bar{x} \leq i\alpha^{-1} \) then \( T(\bar{x}) \in \Psi \). A basically analogous argument proves that \( T([j\alpha^{-1}, \xi_j]) \subseteq \Psi \). Note that by definition, \( \Psi \) is a closed set and we have \( T(\Psi) \subseteq \Psi \subseteq T(\Psi) \), therefore \( \overline{T(\Psi)} = \Psi \).

From the sets described by Proposition 8.1, the smallest of them, this is \( [\zeta_m, \xi_n] \) where \( m = \max\{i : \lambda_{i-1} \leq \zeta_i\} \), and \( n = \min\{i : \xi_i \leq \lambda_i\} \), will be call \( \Omega_{\beta\alpha} \) or \( \Omega \) where the choice of \( \alpha \) and \( \beta \) is clear by context.
8.2 Li-Yorke Theorem and Ergodicity of $T$ for $K = 1$

As it has already been proved, given $\alpha$ and $\beta$ with $\beta > 1$, $\alpha \leq \beta$ and $\beta - \alpha < 1$, and $\Omega$ the smallest of the sets described by Proposition 8.1, we have proven that $\overline{T(\Omega)} = \Omega$. Note that $T$ is a piecewise monotone $C^\infty$ function. Furthermore, if we call $\Omega^*$ the set where both $T$ and $dT/dx$ are continuous,

$$\inf_{x \in \Omega^*} \left| \frac{d}{dx} T(x) \right| > 1.$$  

In [28], Lasota and Yorke proved that under these conditions there exist at least one non-negative function $f$ of bounded variation such that the measure $\mu$ with $d\mu = f dm$ (where $m$ is the Lebesgue measure) is invariant under $T$, in the sense that

$$\mu(E) = \int_E f dm = \int_{T^{-1}(E)} f dm = \mu(T^{-1}(E)).$$

In a more general setting, let's $\tau : I \to I$ is a piecewise continuous and piecewise twice continuous differentiable. Call $I^*$ the set of points where $dT/dx$ exists, and let

$$\inf_{x \in I^*} \left| \frac{d}{dx} \tau(x) \right| > 1. \quad (8.2)$$

We will refer to the points of $I - I^* = \{x_1, \ldots, x_k\}$ as the points of discontinuity. For $x \in I$, let $\Lambda(x)$ be the set of limit points of $\tau^n(x)$, that is

$$\Lambda(x) = \bigcap_{N=1}^{\infty} \{\tau^n(x)\}_{n=N}. \quad (8.3)$$

An important property of this set is that it is a fixed set of $\tau$. This means, $\tau(\Lambda(x)) = \Lambda(x)$. As said before, Lasota-Yorke proves that there are densities invariant under $\tau$. Let $\mathcal{F}$ be the set of $f \in L^1(I)$, such that $f$ is an invariant density under $\tau$. In [30], Li and Yorke proved the following theorem.

**Theorem 8.2** Let $\tau : I \to I$ be a piecewise continuous and twice continuous differentiable interval map satisfying (8.2). Then, there exists a finite collection of sets $L_1, L_2, \ldots, L_n$ and a set of functions $\{f_1, f_2, \ldots, f_n\}$ such that
(1) Each $L_i$ is a finite union of closed intervals,

(2) $L_i \cap L_j$ contains at most a finite number of points when $i \neq j$;

(3) each $L_i$ contains at least one point of discontinuity $x_j$, $1 \leq j \leq k$ on its interior; hence $n \leq k$;

(4) $f_i(x) = 0$ for $x \notin L_i$ and $f(x) > 0$ for almost all $x$ in $L_i$;

(5) $\int_{L_i} f_i(x) dx = 1$ for $1 \leq i \leq n$;

(6) if $g \in F$ satisfy both (4) and (5), then $g = f_i$ almost everywhere;

(7) every $f \in F$ can be written as $f = \sum_{i=1}^{n} a_i f_i$ for suitable chosen $\{a_i\}_{i=1}^{n}$;

(8) for almost every $x \in I$ there is an index $i$ such that $\Lambda(x) = L_i$.

It has been discussed, if $1 < \beta < 2$ and $\beta(\beta - 1) < \alpha < \beta$, $T(x) = \beta x - \lfloor \alpha x \rfloor$ generates a one bit quantization for every $x \in [0,1]$. Now, by Proposition 8.1, $T$ restricted to $\Omega = [\alpha^{-1}\beta - 1, \alpha^{-1}\beta]$. This interval contains a unique point of discontinuity (both of $T$ and its first derivative), and therefore, by Theorem 8.2, up to normalization, there exists a unique non-negative function $f \in L^1$ that generates measure $\mu$ that is invariant under $T$. As this measure is unique, $T$ is ergodic with respect to $\mu$.

Indeed, the density of this function can be given in a closed form. In [35], Parry proved that if $\tau$ is a linear transformation mod 1, (i.e. $\tau(x) = bx + a \mod 1$ for real numbers $a$ and $b$), then the function

$$h(x) = \sum_{x < \tau^n(1)} \frac{1}{\beta^n} - \sum_{x < \tau^n(0)} \frac{1}{\beta^n},$$

where $\tau^0(x) = x$ by definition, is the density of a, potentially signed (but not null) measure.
Note that if $\alpha$ and $\beta$ are the parameters of a one bit quantization scheme, then, we can define $b = \beta$, $a = (\beta - 1)(\beta - \alpha)\alpha^{-1}$, and $f(x) = x - (\beta - \alpha)\alpha^{-1}$, then $T(x) = f^{-1}(\tau(f(x)))$. By Parry’s theorem, we know then that the function

$$g(x) = \sum_{x < T^n(\beta\alpha^{-1})} \frac{1}{\beta^n} - \sum_{x < T^n((\beta-\alpha)\alpha^{-1})} \frac{1}{\beta^n}$$

is the density of an absolutely continuous signed measure on $\Omega$, and by Li-Yorke’s Theorem, such measure is necessarily unique up to a re-scaling factor, therefore, the density of the unique normalized invariant measure under $T$ is

$$f(x) = \left(\sum_{n=0}^{\infty} \frac{T^n(\beta\alpha^{-1}) - T^n((\beta-\alpha)\alpha^{-1})}{\beta^n}\right)^{-1} \left(\sum_{x < T^n(\beta\alpha^{-1})} \frac{1}{\beta^n} - \sum_{x < T^n((\beta-\alpha)\alpha^{-1})} \frac{1}{\beta^n}\right).$$

### 8.3 Ergodicity of $T$ for $K > 1$

We have already proved that, if $K = 1$, then $\Omega$ is a fixed set that possesses an absolutely continuous measure that is invariant under $T$. The natural question at this point is: If $K > 1$, is there a measure $\mu$, that is absolutely continuous with respect to the Lebesgue measure and ergodic with respect to $T$? The answer in general is no.

In Figure 3 we can appreciate the graph of the $\beta\alpha$ encoding function with $\alpha = 3/4$ and $\beta = 3/2$. Under this conditions, $K = 2$ and $\Omega = [1,3]$. Nevertheless, $T$ has two different invariant sets, namely $[1,2]$ and $[2,3]$. Therefore, by Li-Yorke, there is a measure with respect invariant under $T$ for each of these intervals, each one independent on the other, and therefore, for this election of parameters, $T$ is not ergodic.

Indeed, by Li-Yorke, there is one invariant measure for each of those two sets, and their respective densities can be computed in a closed form. Notice that in this case, $\lambda_1$, $\xi_1$ and $\zeta_2$, as defined in (8.1), are all equal. Our simulations suggest that if for every index $i$, the three numbers $\lambda_i$, $\xi_i$ and $\zeta_{i+1}$ are all different, then the system is indeed ergodic, leading us to conjecture the following.
Figure 3: Graph of $T$ with $m$ for $\beta = 3/2$ and $\alpha = 3/4$. Example of $T$ non-ergodic.

Conjecture 8.1 Let $\alpha$ and $\beta$ be two positive real numbers such that $1 < \beta$, $\alpha < \beta$, $\beta - \alpha < 1$. Let $\omega = [1 - (\beta - \alpha)]^{-1}$, $K = [\omega(\beta - 1)] > 1$. Furthermore, assume that neither $\beta^{-1}\alpha\omega$ nor $\beta^{-1}(\beta - 1)\alpha\omega$ are integers and $\beta \neq 2\alpha$. Call $M = [\beta^{-1}\alpha\omega]$ and $N = [\beta^{-1}(\beta - 1)\alpha\omega]$, and let $\Omega = [M\alpha^{-1}(\beta - \alpha), N\alpha^{-1}(\beta - \alpha) + 1]$. Then, $T(\Omega) = \Omega$ and there exists, up to normalization, a unique measure $\mu$ absolutely continuous with respect to the Lebesgue measure that is invariant under $T$. Furthermore, if $f$ is the density of such function, then $\text{supp} f = \Omega$. 
The need to convey all the information contained in a function into a discrete set of values produced what is called today the Sampling Theorem or Shannon-Nyquist Theorem, that was, to the best of the knowledge of the author, first stated and formally proved in [38], by Claude Shannon, although, he does not claim authorship of the result, and writes below the statement: This is a fact that is common knowledge in the communication art. In [33], published in 1928, Harry Nyquist clearly implies the same result, although this is not stated nor formally proved.

On Shannon’s paper, the statement of this theorem reads

**Theorem A.1** If a function $f(t)$ contains no frequencies higher than $W$ cps$^1$, it is completely determined by giving its ordinates at a series of points spaced $1/2W$ seconds apart.

A more modern paraphrasing of the same result would be

**Theorem A.2** If $f(t)$ is a bandlimited function with maximum frequency no higher than $\Omega$, then

$$f(t) = \sum_{k \in \mathbb{Z}} f\left(\frac{k\pi}{\Omega}\right) \text{sinc}\left(\frac{t\Omega}{\pi} - k\right),$$  \hspace{1cm} (A.1)

and thus, $f(t)$ can be fully reconstructed from its samples $f(k\pi\Omega^{-1})$.

The following proof, although not exactly that given in [38], is based in the same ideas.

---

$^1$Cycles per second, now known as hertz, the SI unit for frequency
Proof. To simplify notation, it will be assumed that $\Omega = \pi$. This is just a scaling factor. Consider the Dirac Comb:

$$\Delta(t) = \sum_{k \in \mathbb{Z}} \delta(t - k) = \sum_{k \in \mathbb{Z}} e^{2k\pi it}$$

where $\delta$ is the Dirac delta function. Define the sampled function $f_s(t) = f(t)\Delta(t)$. Note that

$$f_s(t) = \sum_{k \in \mathbb{Z}} f(t)e^{2k\pi it}$$

and thus $
\hat{f}_s(\xi) = \sum_{k \in \mathbb{Z}} \hat{f}(\xi - 2\pi k)$.

By definition, $\hat{f}(\xi) = 0$ if $|\xi| > \pi$, therefore, if $\hat{h}(\xi)$ is the characteristic function of the interval $[-\pi, \pi]$, then, $\hat{f}(\xi) = \hat{f}_s(\xi)\hat{h}(\xi)$. Now

$$h(t) = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{it\xi} d\xi = \frac{1}{2\pi} \cdot \frac{e^{i\pi t} - e^{-i\pi t}}{it} = \frac{\sin \pi t}{\pi t} = \text{sinc} t.$$  

and thus, we can write

$$f(t) = (f_s * \text{sinc})(t) = \sum_{k \in \mathbb{Z}} f(k) \text{sinc}(t - k).$$

The formula in (A.1) is known as the Whittaker-Shannon Interpolation Formula. Although useful, it does not come without drawbacks. As sinc $\notin L^1(\mathbb{R})$, then the right hand side of (A.1) is not, in general, absolutely convergent, and this introduces questions about the proper summation strategy to apply in practice. A way to get around this problem is to introduce a finer sampling rate. The statement, as stated in Chapter 1, reads as follows.

Theorem A.3 (Sampling Theorem) Let $f : \mathbb{R} \to \mathbb{R}$ be a bandlimited function such that $\hat{f}$ is supported in $[-\pi, \pi]$. Let $\lambda > 1$, and $\varphi \in L^1(\mathbb{R})$ such that $\hat{\varphi}$ satisfies

$$\hat{\varphi}(\xi) = \begin{cases} 1 & \text{if } |\xi| \leq \pi, \\
0 & \text{if } |\xi| \geq \lambda \pi. \end{cases}$$  

(A.2)

Then, the following equality holds in the Cesàro mean for all $t$.

$$f(t) = \frac{1}{\lambda} \sum_{n \in \mathbb{Z}} f\left(\frac{n}{\lambda}\right) \varphi\left(t - \frac{n}{\lambda}\right).$$  

(A.3)
The proof of this version of the theorem is a simple modification of previous one. Note that if we call 
\[
\Delta_\lambda(t) = \sum_{k \in \mathbb{Z}} \delta(t - \frac{k}{\lambda}) = \sum_{k \in \mathbb{Z}} e^{2k\lambda \pi it}
\]
and we modify \( f_s(t) = f(t)\Delta_\lambda(t) \), then
\[
f_s(t) = \sum_{k \in \mathbb{Z}} f(t)e^{2k\lambda \pi it} \quad \text{and thus} \quad \hat{f_s}(\xi) = \sum_{k \in \mathbb{Z}} \hat{f}(\xi - 2\lambda \pi k).
\]
Under this condition we still have that \( \hat{f} = \hat{f_s}\hat{\varphi} \), and therefore
\[
f(t) = \frac{1}{\lambda} \sum_{n \in \mathbb{Z}} f\left(\frac{n}{\lambda}\right) \varphi\left(t - \frac{n}{\lambda}\right).
\]
The Cesàro mean convergence is given by Parseval’s formula (see [26, p.35]) for every \( t \). There is another gain of this approach. Let’s consider the space
\[
S(\mathbb{R}) = \left\{ f \in C^\infty(\mathbb{R}) \left| \lim_{x \to \infty} x^\alpha \frac{d^n f}{dx^n}(x) = 0, \forall \alpha \in \mathbb{R}, n \in \mathbb{Z}, n \geq 0 \right. \right\}.
\]
This is called the Schwartz space. It is a known fact that the Fourier transform is an isomorphism of \( S(\mathbb{R}) \) to itself (see [16, p.74]). With this approach, it is possible to choose \( \hat{\varphi} \) in (A.2) to be \( C^\infty \), and thus, an element of \( S(\mathbb{R}) \), and therefore so would be \( \varphi \), ensuring the absolute convergence of the right hand side of (A.3).
APPENDIX B

NUMERICAL RESULTS FOR WNH

Here we present data from our computer experiments comparing the ideal \( \text{MSE} \) to the actual \( \text{MSE} \). We have performed Monte Carlo simulations for several different sets of frames. We also experimented with various distributions for \( x \in \mathbb{R}^d \). As it turns out, we get very similar results for the distributions we used for most of the frames we tried. In the examples shown, the random vectors \( X \) are all chosen to be uniformly distributed in \([-5, 5]^d\).

**Example B.1** Let \( \{v_j\}_{j=1}^N \) be the harmonic frame in \( \mathbb{R}^2 \), with

\[
v_j = \begin{bmatrix} \cos \frac{2\pi j}{N}, \sin \frac{2\pi j}{N} \end{bmatrix}^T.
\]

This is a tight frame with frame constant \( \lambda = \frac{N}{2} \). The ideal \( \text{MSE} \) is \( \frac{\Delta^2 \lambda}{3N} \) for \( N \) odd. Taking \( \Delta = \frac{1}{2} \), Table 1 displays the actual \( \text{MSE} \), the ideal \( \text{MSE} \) and the ratio between them. It shows that as \( N \) gets larger than 129, the actual \( \text{MSE} \) does not improve, which shows that the WNH is invalid for large \( \Delta \).

**Example B.2** Let \( \{v_j\}_{j=1}^N \) be \( N \) independently and randomly generated vectors uniformly distributed on the unit sphere in \( \mathbb{R}^4 \). Table 2 shows the ratio between the actual \( \text{MSE} \) and the ideal \( \text{MSE} \), where \( \text{MSE}_{\text{ideal}} = \frac{\Delta^2}{12} (\sum_{j=1}^d \lambda_j^{-1}) \), with \( \Delta = 2^{-k} \).

**Example B.3** Let \( \{v_j\}_{j=0}^{N-1} \) be the harmonic frame in \( \mathbb{R}^4 \), with

\[
v_j = \sqrt{\frac{1}{2}} \begin{bmatrix} \cos \frac{2\pi j}{N}, \sin \frac{2\pi j}{N}, \cos \frac{4\pi j}{N}, \sin \frac{4\pi j}{N} \end{bmatrix}^T.
\]

This is a tight frame with frame constant \( \lambda = \frac{N}{4} \), and the ideal \( \text{MSE} \) is \( \frac{4\Delta^2}{3N} \). Table 3 shows the ratio between the actual \( \text{MSE} \) and the ideal \( \text{MSE} \) where \( \Delta = 2^{-k} \).
Table 1: The Harmonic frame in $\mathbb{R}^2$

Example B.4 Let $\{v_j\}_{j=1}^5$ be a frame in $\mathbb{R}^3$, with the corresponding matrix

$$F = \begin{pmatrix}
1 & 1 & 1 & 2 & -3 \\
1 & -1 & -1 & 2 & -3 \\
1 & 0 & -1 & 2 & -3
\end{pmatrix}$$

Note that the set contains many parallel vectors. The MSE under the WNH is $0.2946\Delta^2$ and by our result, the ideal MSE is $0.2959\Delta^2$. The difference is not significant, as with most of such cases. It is rather intuitive to see that the second part in (4.11) contributes only a small portion of the whole MSE. Table 4 shows the actual MSE, the ideal MSE, and the ratio between the actual MSE and the ideal MSE, where $\Delta = 2^{-k}$.
