PROGRESS REPORT NO. 1

THE KINETICS AND SPECTROSCOPY OF AIRCRAFT AND ROCKET PLUME CONSTITUENTS

By
Dr. F. P. Tully
Dr. A. R. Ravishankara
Co-Principal Investigators

Prepared for
AIR FORCE OFFICE OF SCIENTIFIC RESEARCH
CONTRACT NO. F 49620-77-C-0111

June 1, 1977 – May 31, 1978

GEORGIA INSTITUTE OF TECHNOLOGY
Engineering Experiment Station
Atlanta, Georgia 30332

1978
Chemical kinetic studies of relevance to aircraft and rocket exhaust plume characterization are in progress. These investigations are divided between two topic areas: (1) hydroxyl radical - small molecule rate constant measurements, and (2) kinetic and mechanistic probes of oxidant - haloborane reactions. These topic areas are described individually below.

I. Hydroxyl Radical - Small Molecule Rate Constant Measurements

Using the technique of flash photolysis - (resonance/laser induced) fluorescence, we are measuring absolute rate constants for Reactions (1) - (4) over the indicated temperature intervals.

\[
\begin{align*}
\text{OH} + \text{H}_2 &\longrightarrow \text{H}_2\text{O} + \text{H} \quad (500 - 1200K) \quad (1) \\
\text{OH} + \text{CH}_4 &\longrightarrow \text{H}_2\text{O} + \text{CH}_3 \quad (500 - 1200K) \quad (2) \\
\text{OH} + \text{CO} &\longrightarrow \text{H} + \text{CO}_2 \quad (500 - 1000K) \quad (3) \\
\text{OH} + \text{CH}_2\text{O} &\longrightarrow \text{H}_2\text{O} + \text{CHO} \quad (300 - 800 K) \quad (4)
\end{align*}
\]

In these experiments, a spark discharge through an inert gas produces a radiation flash composed of wavelengths from the vacuum ultraviolet through the visible spectral regions. The radiation flash is transmitted to the reaction cell in which H2O is photolyzed to produce H and OH species. The post-flash temporal behavior of the OH concentration is then monitored via resonance/laser-induced fluorescence.

A block diagram of the overall reaction kinetics system is shown in Figure 1. The basic components of this system are: (1) a thermostated reaction cell centered in a vacuum housing, (2) a spark discharge flashlamp perpendicular to one face of the cell, (3) a resonance lamp (or probe laser) perpendicular to another face of the cell, (4) a photodetector perpendicular
Figure 1. Reaction Kinetics System
to the base of the cell, and (5) fast photon counting electronics, including a multichannel analyzer which provides up to 1 μsec time resolution and signal averaging capabilities.

To this point in time, all of the data on Reactions (1) - (4) which we have collected has been obtained using resonance lamp excitation of OH fluorescence. We have found, not surprisingly, that as the reaction temperature is raised the OH radical detection sensitivity decreases markedly. Factors such as increasing nonradiative collisional deactivation of the $A^2\Sigma^+$ state of OH, decreasing usable H$_2$O number densities and decreasing optical transmission to and from the reaction zone contribute to this diminution of detection sensitivity at higher temperatures. Sensitivity limitations have necessitated several modifications of our initial experimental configuration: (1) improved quartz lens focussing of the resonance radiation; (2) teflon blackening of the inside of the vacuum housing so as to minimize scattered resonance radiation; (3) improved collimation and cooling throughout the system; and (4) installation of counting electronics linear up to pulse rates of 20 MHz. As we approach 1000K experiments, further improvements are in the works. We plan to install a quartz light pipe between the resonance lamp and the quartz focussing lens attached to the reaction cell. We also plan to add a quartz focussing lens at the base of the reaction cell to improve the photomultiplier collection efficiency. Two possible further changes are also receiving consideration: (1) replacement of the flowing inert gas spark discharge flashlamp by a closed xenon flashlamp, and (2) purchase and installation of a new Varian photomultiplier tube having nearly twice the quantum efficiency at 3100Å of our present RCA 8850 photodetector.

Two other approaches to this detection sensitivity problem are also
receiving attention. During this contract period, a 4-watt Lexel argon ion laser and an assortment of mirror mounts and optical components were purchased using State of Georgia funds. Intracavity doubled and extracavity doubled cw ultraviolet dye laser systems were built and tuned to an OH fluorescence excitation wavelength at 3082.5 Å. Use of such a cw laser probe to excite OH fluorescence would be extremely advantageous since the scattered light background so characteristic with resonance lamp excitation could be almost totally negated. At present, however, due to low power densities and a high-loss doubling crystal, insufficient usable photon flux has been obtained. Future modifications of this laser probe must therefore involve construction of an intracavity doubled ring dye laser system. Progress toward this end will depend on the availability of in-house funds.

An alternative laser-based approach involves the use of our high-power pulsed Quantel YG-481A Nd/Yag laser. Since harmonic generation efficiencies are proportional to power densities, frequency doubling of pulsed tunable dye laser radiation would certainly provide sufficient radiant flux to excite the needed OH fluorescence levels. Unfortunately, such a transition from a cw detection system to a pulsed detection system greatly hinders the obtainable duty cycle of the kinetic measurements. One would have to trigger the firing of the exciting laser probe at various fixed times following the initiating photolysis flash in order to generate a concentration vs. time profile. Normalization constraints would thus also become much more severe. Realization of this detection system, then, though tremendously promising, is still quite some time off.

During this contract year, then, our efforts within this topic area have been interactively time-shared between data acquisition and detection technology improvement. Using our present resonance lamp excitation
detection mode, quality rate constant measurements are accessible to tempera-
tures of 1000K. In the following paragraphs, preliminary rate con-
stant data for Reactions (2) and (3) up to temperatures in excess of 800K
will be discussed. Following the presentation of these results, the status
of our studies of Reactions (1) and (4) will be discussed.

Figure 2a presents a typical example of our measured OH concentration
vs. time profiles (following scattered light background subtraction) in the
absence and presence of molecular reactant. In the pseudo-first order
kinetic approximation, the measured pseudo-first order decay constant, \( k_{\text{exp}} \),
is given by the expression

\[
k_{\text{exp}} = k_{\text{bi}}[\text{Reactant}] + k',
\]

where \( k_{\text{bi}} \) is the bimolecular rate constant for the reaction \( \text{OH} + \text{Reactant} \rightarrow \text{Products} \) and \( k' \) represents the rate of loss of OH from the viewing zone of
the photomultiplier in the absence of the subject reactant. The value of
\( k_{\text{bi}} \) is then determined from the slope of a plot of \( k_{\text{exp}} \) vs. \([\text{Reactant}]\).
For the \( \text{OH} + \text{CO} \rightarrow \text{H} + \text{CO}_2 \) reaction at 511K, such a plot, typical for our
measurements, is displayed in Figure 2b.

Absolute rate constant vs. temperature data for Reaction (2) is
listed in Table I and plotted in Arrhenius form in Figure 3. Analogous
measurements for Reaction (3) are listed in Table II and plotted in Arrhen-
ius form in Figure 4. The precision for all of these measurements is 15%
or better. These numbers should nevertheless be considered preliminary
for two reasons: (1) for the most part least squares analyses of the OH
decay rates and the \( k_{\text{exp}} \) vs. \([\text{Reactant}]\) plots have not yet been performed,
and (2) at a limited number of temperatures, measurements at one or two
OH + CO → H + CO₂ (511 K)

Figure 4
more reactant concentrations are desired.

Our results for Reaction (2), OH + CH₄ → H₂O + CH₃, are in qualitative agreement with the flash photolysis-resonance absorption measurements of Zellner and Steinert.² Curvature in the Arrhenius plot is observed, though the degree of such curvature appears substantially less severe than that reported in Reference 2. A closer examination of this comparison will be presented in future reports.

Our rate constant measurements for Reaction (3), OH + CO → H + CO₂, are in very close agreement with those calculated from the analytical expression recommended in the recent review of Baulch et al.³ The low-temperature regime activation energy for this reaction is indeed very small.

Although a substantial number of experiments have been performed on the kinetics of Reaction (1), OH + H₂ → H₂O + H, we have not included those results in this report. The precision of these rate constant measurements has not been as good as that obtained in the studies of Reactions (2) and (3). We feel that a number of these experiments require thorough reinvestigation prior to the dissemination of these results.

Kinetic studies of Reaction (4), OH + CH₂O → H₂O + CHO, are just beginning in earnest. For these experiments it has proven to be necessary to synthesize monomeric formaldehyde from paraformaldehyde. Because water is known to catalyze the polymerization of formaldehyde, only small quantities of this photolytic source can be tolerated. [At low temperatures, OH will be formed in the presence of CH₂O by 2650Å laser photolysis of an O₃/H₂/CH₂O mixture.] We expect, then, to have to live with very small signals (and much averaging) in the higher temperature regime of this experiment where H₂O is used as the photolytic source of OH.
In the next few months we expect to extend the temperature intervals of measurement for these reactions and, in particular, address the study of Reactions (1) and (4) in much more detail. An analogous study of the OH + C₂H₆ → H₂O + C₂H₅ reaction is planned during the second year of the contract.

II. Oxidant-Haloborane Studies

The achievement of an understanding of the oxidation characteristics of halogenated boron species is essential to the estimation of the concentrations of boron molecular emitters present in advanced fuel rocket plume exhausts. Knowledge of the typical concentrations of emitting species is a prerequisite to the interpretation of rocket plume infrared signatures. Since very little is known about haloborane oxidation (and also about the technology required for its study), we have initiated studies of relevant molecular reactions with the aim of developing experimental techniques permitting future investigation of the more complex radical reactive systems.

In the work statement for this program, we have contracted to measure absolute rate constants for Reactions (5) and (6),

\[ O_2 + BF_3 \rightarrow \text{Products} \tag{5} \]
\[ O_2 + BCl_3 \rightarrow \text{Products}, \tag{6} \]

using the technique of stop-flow time-of-flight mass spectrometry. A schematic diagram of this technique is displayed in Figure 5. In this system a thermostated reaction vessel equipped with a very small molecular leak is positioned directly above the ion source of a time-of-flight mass spectrometer. Reactants are admitted to the vessel and mix homogeneously

and reach temperature equilibrium within a few milliseconds. Following mixing, the reaction is occurring at the desired conditions of temperature, pressure and reactor composition. The molecular leak at the bottom of the reaction cell allows a very small fraction of the cell contents to diffuse into the ion source of the mass spectrometer. This effluent is ionized, the ions are accelerated to constant energy, and the ion current and time of arrival at the detector are measured. The entire spectrum can be cycled every 100 μsec. In essence, this technique allows the determination of the cell contents in real time. In a kinetic experiment, however, only one ion, produced upon ionization of either a reactant or product molecule, is monitored with time. The temperature range of our stop-flow system is 250K - 450K. Second order reaction rate constants between $2 \times 10^{-23}$ cm$^3$ molec$^{-1}$ sec$^{-1}$ and $5 \times 10^{-17}$ cm$^3$ molec$^{-1}$ sec$^{-1}$ are amenable to accurate measurement within this system. Since this range of rate coefficients corresponds to that expected for many molecule-molecule reactions, this technique was proposed for the study of Reactions (5) and (6).

When stop-flow time-of-flight mass spectrometry experiments were performed on Reactions (5) and (6), it was found that within experimental error addition of one reactant to the reaction vessel had no effect on the rate of disappearance of the other reactant. We thus estimated that the rate constants for these processes are $\leq 1 \times 10^{-23}$ cm$^3$ molec$^{-1}$ sec$^{-1}$.

Having found that the rate constants for Reactions (5) and (6) are too slow to be measured by the above technique, we devised a time-resolved infrared spectroscopy study of these reactions. An optical absorption cell seasoned with the haloborane prior to each experiment was filled with a few torr of the haloborane and 350 - 500 torr of oxygen. Haloborane in-
Infrared absorption intensities were then monitored as functions of time. Typical results of these experiments are plotted in Figure 6. The haloborane decay rates are seen to be extremely slow and, because wall loss effects may have been contributing to the observed decays, the rate constants extracted from these pseudo-first order decays must be considered as upper limits. Our knowledge of these rate constants thus remains limited to the expressions $k_5 \leq 1 \times 10^{-30}$ cm$^3$ molec$^{-1}$ sec$^{-1}$ and $k_6 \leq 4 \times 10^{-25}$ cm$^3$ molec$^{-1}$ sec$^{-1}$.

Having observed nearly negligible reactivities for the reactions $O_2 + BF_3/BCl_3$, we decided to probe the general oxidative behavior of the haloboranes in more detail by studying their reactions with more active oxidizing agents. Investigations of the following reaction processes were made:

\[ O_3 + BF_3 \rightarrow \text{Products} \]  (7)
\[ O_3 + BCl_3 \rightarrow \text{Products} \]  (8)
\[ H_2O + BCl_3 \rightarrow \text{Products} \]  (9)

Again using the technique of time-resolved infrared spectroscopy, Reaction (7) was investigated and found to be immeasurably slow at room temperature. This reaction, then, was not looked at further. The study of Reaction (8), on the other hand, proved to be very interesting. Time-sequenced sets of complete infrared spectra of reacting $O_3/BCl_3/Ar$ mixtures were taken. The initial $BCl_3$ and argon pressures were measured using a capacitance manometer and the initial $O_3$ pressure was calculated from uv absorption measurements made at 313 nm. The initial reactant partial pressures were varied by as much as factors of four in different runs. The $BCl_3$ and $O_3$ decay

Figure 6. Time-Resolved Infrared Spectroscopy
rates and reaction product buildup rate (as shown in Figure 7a, a reaction product peak not observed in the pure O₃ or pure BCl₃ spectra grows with time) are calculated from the peak intensities in the sequential infrared spectra. Relative concentration vs. time after mixing plots for a typical experimental run are displayed in Figure 7b. It is seen that the rate of growth of the reaction product closely images the rate of decay of the BCl₃ reactant. It is worth noting here, however, that the bimolecular rate constants calculated from such plots do show a slight tendency to increase with increasing [O₃]₀/[BCl₃]₀ ratios. These variations are likely due to the overall stoichiometry of the reaction.

Three other experimental techniques were applied to the study of Reaction (8): (1) time-resolved uv absorption spectroscopy, (2) stop-flow time-of-flight mass spectrometry, and (3) reaction end product analysis. The results of these studies will be discussed below in turn.

A schematic diagram of the simple but very powerful technique of time-resolved uv absorption spectroscopy is given in Figure 8a. Light from a mercury lamp at 2537Å was passed through an absorption cell containing the O₃/BCl₃/Ar mixture. The transmitted intensity was monitored as a function of time by a filtered photodiode. Experiments were run with [BCl₃] in varying excesses over [O₃], ozone being the monitored species. Use of this technique required considerable caution. Since 2537Å radiation is absorbed by ozone via the photodissociative reaction O₃ \( \rightarrow \) O(\(^{1}\)D) + O₂, the possibility existed that the atomic oxygen formed in the probe process could contribute to the chemistry under study. By using a variety of ozone concentrations and 2537Å radiation fluxes, however, it was conclusively shown that such probe-induced processes were unimportant. Furthermore, by allowing the low concentration reactant ozone to undergo complete

\]

Figure 8b
reaction and then measuring essentially no absorption of 2537Å radiation, it was clearly demonstrated that the products of the reaction were not absorbing the probe radiation and thereby biasing the kinetic results. Thus the time variation of the transmitted 2537Å intensity generates an accurate time history of the ozone concentration. The experiments were run under pseudo-first order conditions with BC13 in excess and, as shown in Figure 8b, the bimolecular rate constant was obtained as the slope of a plot of the pseudo-first order decay constant vs. the BC13 concentration. A value of $k_{b1} (298K) = 8.31 \times 10^{-21} \text{ cm}^3 \text{ molec}^{-1} \text{ sec}^{-1}$ was obtained.

Reaction (8) was also studied by the previously described technique of stop-flow time-of-flight mass spectrometry. Small concentrations of BC13 in varying excesses of ozone were mixed in the reaction vessel and the time variation of the BC12$^+$ ion was followed mass spectrometrically. Typical decay curves are shown in Figure 9a; a bimolecular rate constant of $k_{b1} = 1.2 \times 10^{-20} \text{ cm}^3 \text{ molec}^{-1} \text{ sec}^{-1}$ was calculated by the usual methods. Averaging this result with that obtained using time-resolved uv absorption spectroscopy techniques, one obtains a room temperature rate constant for Reaction (8) of $k_{b1} = (1.0\pm0.3) \times 10^{-20} \text{ cm}^3 \text{ molec}^{-1} \text{ sec}^{-1}$. It is worth noting here that this value exceeds that obtained in the time-resolved infrared spectroscopy experiments (see Figure 7) by about a factor of six. Though we do not feel that we can adequately explain this discrepancy, it is probable that it is at least in part related to wall absorption of ozone in the extended duration infrared spectroscopy experiments.

Mass spectrometric studies of Reaction (8) were also performed by time sequenced sweeps of the entire mass spectrum. From top to bottom, Figure 9b shows respectively the mass spectrum obtained for pure ozone, that obtained for pure BC13, and that obtained a substantial period of

STOP-FLOW T.O.F. MASS SPECTROMETRY
time after mixing a small concentration of BCl₃ with a large excess of ozone. Close examination reveals that the observed product patterns differ substantially from the superposition of the pure O₃ and pure BCl₃ traces. In Table III we have listed those significant mass peaks observed in the mixed O₃/BCl₃ system which were found to be of only minor importance in either pure spectrum. Species such as BO, BO₂, BC10, Cl₂ and HCl have been identified. Other significant mass peaks remain unassigned at this time.

Finally, an end product analysis investigation of Reaction (8) was undertaken. Ozone and BCl₃ were mixed in a reaction vessel and allowed to react to completion. The techniques of infrared and uv absorption spectroscopy and expansion of condensable and non-condensable gases into calibrated volumes were utilized in the product analysis. As can be seen in Table IV, the loss of BCl₃ molecules was found to be about 2/3 that of the gain in Cl₂ molecules: chlorine balance seems assured through the formation of Cl₂. Since the number of condensable boron oxide molecules formed could not be measured, the boron and oxygen balances cannot be definitively assigned. One notices, however, that the loss of ozone molecules exceeds the loss of BCl₃ molecules, possibly by as much as a 3:2 ratio. If such stoichiometry is assumed, then the overall Reaction (8) mechanism could be represented by reaction expressions of the type (or linear combinations thereof) listed at the bottom of Table IV.

An abbreviated stop-flow time-of-flight mass spectrometry study was also performed on Reaction (9). This reaction was found to be fast, probably heterogeneous, and produced HCl and condensable boron oxides in high yield. Indeed, the addition of pure BCl₃ to a reaction vessel which had previously contained H₂O resulted in both the fast decay of BCl₃ and the

$$\text{B}_2\text{O}_5(?)$$
obvious formation of HCl. In experiments in which BCl₃ and H₂O were mixed in the gas phase, the molecular leak of the reaction vessel very quickly became clogged resulting in the termination of gas flow into the mass spectrometer analyzer.

The above described studies of Reactions (5) through (9) have resulted in some interesting information concerning the general oxidative behavior of the haloboranes. Equally important, they have provided sufficient knowledge to make possible studies of more plume-relevant processes such as the radical-molecule reaction

\[
O(^3P) + BF_3 \rightarrow \text{Products} .
\]  

(10)

Absolute rate constant measurements for Reaction (10) will be undertaken in the second year of this program. The high concentrations of the O(^3P) species found both in plumes and in the upper atmosphere render this reaction of probable importance to infrared signature interpretation. Furthermore, as a step toward technology development, Reaction (10) may provide valuable information on future kinetic methods for studying reactions involving species such as BF₂, BF, BO, BO₂, BOF, etc. Reactions such as those listed in the November 15, 1977 Grumman Aerospace Corporation Compilation (Contract #F04611-77-C-0054) cannot be kinetically defined until clean methods of producing the subject reactant molecular species are found.
1. Replacement of the flowing nitrogen spark discharge flashlamp by a closed xenon flashlamp is under consideration. During the hydroxyl radical reaction experiments, a period of time elapsed within which photon signals due entirely to flashlamp firing were detected over time intervals of 30 msec or more. These observations were made with the resonance lamp off and the vacuum housing empty and sealed. Since 30 msec is often long enough to follow several 1/e reactant decay periods, we had little success running experiments with these interfering conditions. Initially we postulated three possible explanations: (1) the flash duration had become greatly extended over its typical ~20 μsec value; (2) contamination in the flashlamp line was causing an 'afterglow fluorescence' to be emitted from the flashlamp; and (3) flashlamp radiation was inducing long-lived fluorescence emission from the vacuum housing walls, interference filter, etc. None of these explanations proved to be correct. Indeed, the more we cleaned our components the worse the problem became. Eventually, in analogy with superradiant phenomena in nitrogen gas lasers, we realized that our nitrogen stream was so pure that we were observing 'active nitrogen' fluorescence over the 30 msec interval following the 20 μsec flashlamp firing duration. [This emission is inconveniently located near 310-320 nm, explaining its passage through our bandpass filter.] Addition of small traces of oxygen to the spark discharge gas stream allows the afterglow duration to be reduced to 3-5 msec. Unfortunately, oxygen addition also quenches the vacuum ultraviolet emission intensity from the flashlamp, thereby decreasing overall signal levels. Furthermore, because of this 3-5 msec 'afterglow', it is sometimes necessary to reject data from the first few milliseconds following the photolysis flash. Since for large values of k_{exp} (increasingly prevalent as k increases at higher temperatures) this time interval corresponds to a good fraction of one 1/e reactant decay period, considerable extra signal averaging becomes necessary upon such data rejection. Use of a xenon flashlamp should eliminate this problem entirely.

ABSTRACT

During the past year particularly striking progress has been made toward the dual objectives of this program: 1) to measure absolute rate constant temperature dependences for radical-molecule reactions of specific importance to modelling of combustion and plume processes in aircraft and rockets; and 2) to contribute to the general understanding of the temperature dependence of bimolecular reactions, particularly as related to observed curvature in Arrhenius plots. Improved sensitivity in the flash photolysis-resonance fluorescence technique was achieved and high-accuracy rate constant measurements were made in the heretofore only marginally accessible 500-1000K temperature regime. Kinetic data for the important reactions \( \text{OH} + \text{H}_2, \text{CH}_4, \text{CO}, \) and \( \text{C}_2\text{H}_6 \) was obtained and promising future experiments were thereby defined.
INTRODUCTION

Aircraft and rocket exhaust plumes provide an energetic, highly non-uniform, local environment within which microscopic physical and chemical processes act to dictate the nature of bulk observations of the medium. Analyses of fuel performance and tracking procedures rely on modelling of those contributing processes which, in combination, govern the efficiency of the propulsion system or surveillance method under examination. Chemically, reactions within the combustor and afterburning within the plume place heavy demands on the estimating prowess of kinetic modellers. In most cases, it is simply not possible to calculate which among the myriad of possible processes are most important (and thus which among the possible molecular species are of greatest concern)—an extensive data base, promoting realistic modelling parameter limitations, is needed. From a kinetic standpoint, optimized acquisition of this data base implies the measurement of oxidant/fuel/reaction intermediate reaction rate constants needed directly for model input and/or required as bases for the generation of 'global' kinetic equations applicable to entire families of chemical reactions. Improvement of the understanding of those factors which govern the temperature dependence of combustor/plume relevant bimolecular reactions is the primary goal of this research program.

PROGRESS SUMMARY

Historically speaking, our modern view of the temperature dependence of the rate constant for bimolecular gas-phase reactions originated with Arrhenius' model in 1889.\(^1\) Arrhenius' postulated equation, \(k(T) = A\exp(-E_a/RT)\), endured as law into the 1960s. The development of improved experimental
techniques applicable over extended temperature ranges of measurement then
spawned a large number of intercomparable studies and led to the initial
clear case of failure of Arrhenius' equation. Even up through the past
few years, however, such failures were typically characterized merely by
noting, for a particular reaction, substantial disagreement between the
log k(T) vs. 1/T slopes obtained as the high-temperature (T > 1000K) and
low-temperature (T < 500K) straight-line extrapolations. It has not been,
in the past decade, that curvature in the log k(T) vs. 1/T (so-called
Arrhenius) plot is unacceptable; theoretically, curvature has been con-
sidered likely for some time. The lack of sufficient congruence of data
in either (high or low) temperature regime and the nearly total absence
of reliable rate constant data between 500K and 1000K has delayed until
quite recently and limited to just a very few reactions even the empirical
smooth joining of high and low temperature measurements.

It is precisely that void in elementary reaction rate constant measure-
ments from 500K - 1000K that has inspired the development and growth of
this research program. During the past year, accurate extended temperature
range rate constant measurements have been made for the following reactions:

\[
\begin{align*}
\text{OH} + \text{H}_2 & \xrightarrow{k_1} \text{H}_2\text{O} + \text{H} \\
\text{OH} + \text{CH}_4 & \xrightarrow{k_2} \text{H}_2\text{O} + \text{CH}_3 \\
\text{OH} + \text{CO} & \xrightarrow{k_3} \text{H} + \text{CO}_2 \\
\text{and} & \quad \text{OH} + \text{C}_2\text{H}_6 \xrightarrow{k_4} \text{H}_2\text{O} + \text{C}_2\text{H}_5
\end{align*}
\]

Distinct curvature in the Arrhenius plot, varying in degree, has been
observed for each Reaction (1) - (4).
Our results for Reaction (1) are listed in Table I and are plotted individually and in combination with selected other results in Figures 1 and 2, respectively. Our measurements demonstrate that the degree of curvature in the Arrhenius plot for Reaction (1) exceeds that predicted by the expression of Cohen and Westberg. Cohen and Westberg's empirical fit was generated primarily by interpolative joining of immense numbers of measurements (not shown in Figure 2) in the low and high temperature regimes. Thus, even though the kinetics of Reaction (1) has received enormous attention over the years, the previous scarcity of data from 500-1000K has limited the reliability of the best obtainable empirical fits for $k_1(T)$.

Absolute reaction rate constant measurements obtained for Reaction (2) are listed in Table II and plotted in Figures 3 and 4. Many important general features are evident from Figure 4. First, it can be seen that straight-line extrapolations of either the low-temperature based (NASA, troposphere and stratosphere) recommendation or the high-temperature based (Peeters and Mahnen best fit) recommendation produce order of magnitude errors in $k_2(T)$ in the opposing temperature regimes. Clearly, even for approximate modelling efforts, curvature in the Arrhenius plot cannot be ignored. Second, it is interesting to contrast the data of Zellner and Steinert with Zellner's subsequently obtained forced empirical fit to the existing high- and low-temperature data (solid line in Figure 4). Using the direct experimental technique of flash photolysis-resonance absorption, Zellner and Steinert measured $k_2(T)$ up to temperatures of 892K. At lower temperatures, this data agrees well with the empirical fit, but, at higher temperatures, their measured $k_2(T)$ values exceed the best fit values by a factor increasing with temperature and already more than two

at 900 K; indeed, Zellner was forced to attach minimal weighting to his own measurements to attain agreement with high-temperature measurements such as those of Peeters and Mahnen. In contrast, our $k_2(T)$ values reported above lie dead-on Zellner's empirical expression, verifying both the adequacy of the functional form, $k(T) = AT^n\exp(-E_a/RT)$, and the basic soundness of previous measurements in both temperature regimes. Our flash photolysis-resonance fluorescence technique, then, appears more appropriate to higher temperature investigations than the flash photolysis-resonance absorption method of Zellner and Steinert. Although both experiments measure the disappearance of OH radicals in real time, the absorption technique monitors the difference between two large numbers $[(I_{t=0} - I_t)/I_{t=0}]$, and thus requires larger OH concentrations to match the statistics obtainable from the fluorescence technique. Such larger radical concentrations enhance the probability of OH disappearance due to processes other than Reaction (2).

Experimental measurements of $k_3(T)$ for Reaction (3) are listed in Table III and plotted in Figure 5. The OH + CO → H + CO$_2$ reaction is of extreme importance. In combustion processes, Reaction (3) represents the principal mode of conversion of CO to CO$_2$; since this reaction is very exothermic, its kinetics considerably impact the time profile for combustive energy release, and thereby, factors such as ignition, acceleration and propagation of flames. Also in the atmosphere, Reaction (3) is the principal CO + CO$_2$ conversion pathway; its kinetics and possible pressure dependence thus impact numerous important atmospheric chemicals cycles (e.g., NO → NO$_2$). The pictorial effect of the curvature in the Arrhenius plot for Reaction (3) is quite dramatic. At low temperatures, the activation energy for this reaction is

near zero; at higher temperatures, $k_3(T)$ increases rapidly with temperature.

[It is worth noting here that visual comparisons of the 'degree' of curvature in Arrhenius plots for several reactions can be misleading; for a reaction where the low-temperature rate constant itself depends strongly on temperature, e.g., $OH + CH_4 \rightarrow H_2O + CH_3$, substantial high-temperature rate constant enhancement may be perceived as only moderate curvature.] As in our studies of Reactions (1) and (2), our measurements of $k_3(T)$ fill the gap between 500 K and 1000 K and verify the adequacy of the empirical forced fit expression of Baulch, et al.\textsuperscript{7} \hspace{1cm} Our measurements of $k_3(T)$ above 900 K lie slightly above the solid line in Figure 5; it would be worthwhile to remeasure and extend $k_3(T)$ to the 1200 K temperature regime.

Rate constant data for Reaction (4), $OH + C_2H_6 \rightarrow H_2O + C_2H_5$, is tabulated in Table IV and plotted in Figures 6 and 7. Prior to these measurements, the only reliable rate constants existing for this reaction were a few measurements at and slightly above room temperature. Once again, it can be seen from Figure 7 that straight-line extrapolation of low-temperature measurements\textsuperscript{8} results in an underestimation of the bimolecular rate constant $k_4(T)$ at higher temperatures; concave upward curvature is again evident.

The chemical kinetics experiments described above represent valuable new input to current models of hydrocarbon combustion processes. Reactions (1) through (3) are of such fundamental importance to hydrocarbon oxidation chains that accurate characterization of these $k_j(T)$ functions is, in itself, a goal of considerable significance. Kinetic estimates for Reactions (1) - (3) pervade hydrocarbon combustion modeling efforts; use of incorrect input could modify the bulk observable results of a simulated model process to an extent which implies that the assumed model structure is wrong - this may be the case, or the problem could be in the inaccuracy of the data base.

FIGURE 7
Yet one should not assume that the value of these results (and of our developed experimental technique) is limited to the numerical achievements detailed above. Typically, the complexity of the chemistry involved in a combustion and/or plume process is nearly overwhelming. In recent years it has become increasingly obvious that it is simply not possible to measure the kinetic parameters for all contributing elementary reactions in a complex process. Indeed, if such a data base did exist, computational limitations would prevent its full utilization. Increasing attention is thus being focused on the generation of 'global' kinetic equations, i.e., kinetic expressions which are approximately applicable to families of analogous chemical reactions. Such a viewpoint then argues the need for investigations which emphasize the effects of chemical structure on the rates of reactivity; studies aimed at generating an improved understanding of the general temperature dependence of bimolecular reaction rates must be pursued. Investigations of Reactions (1)-(4) and our planned experiments on processes such as

\[

Although most of these experiments have been performed by the Co-
Principal Investigators, undergraduate student assistants have made
significant contributions to the execution of this program. In particular,
students

K. Carr - part-time assistant and Special Projects
Researcher in Chemistry

R. Thompson - Cooperative Division Student

have benefited the program and benefited from their experience.
Utilizing the technique of flash photolysis-resonance fluorescence the rate constants for the reactions of hydroxyl radicals (OH) with hydrogen, methane, carbon monoxide and ethane were measured at elevated temperatures as high as 1020K. Distinct curvature was observed in the Arrhenius plots for all four reactions. The measured rate constants were compared with previous measurements in the literature. Future measurement plans were outlined.

INTRODUCTION

Aircraft and rocket exhaust plumes provide an energetic, highly non-uniform, local environment within which microscopic physical and chemical processes act to dictate the nature of bulk observations of the medium. Analyses of fuel performance and tracking procedures rely on modelling of those contributing processes which, in combination, govern the efficiency of the propulsion system or surveillance method under examination. Chemically, reactions within the combustor and afterburning within the plume place heavy demands on the estimating prowess of kinetic modellers. In most cases, it is simply not possible to calculate which among the myriad of possible processes are most important (and thus which among the possible molecular species are of greatest concern). Therefore, an extensive data base, promoting realistic modelling parameter limitations, is needed. From a kinetic standpoint, optimized acquisition of this data base implies the measurement of oxidant/fuel/reaction intermediate reaction rate constants needed directly for model input and/or required as bases for the generation of 'global' kinetic equations applicable to entire families of chemical reactions. Improvement of the understanding of those factors which govern the temperature dependence of combustor/plume relevant bimolecular reactions is the primary goal of this research program.

PROGRESS SUMMARY

Historically speaking, our modern view of the temperature dependence of the rate constant for bimolecular gas-phase reactions originated with Arrhenius' model in 1889 [1]. Arrhenius' postulated equation, $k(T) = A \exp\left(-\frac{E_a}{RT}\right)$, endured as law into the 1960's. The development of improved experimental techniques applicable over extended temperature ranges of measurement
then spawned a large number of intercomparable studies and led to the initial clear case of failure of the simple Arrhenius' equation. Even up through the past few years, however, such failures were typically characterized merely by noting, for a particular reaction, substantial disagreement between the log \( k(T) \) vs. \( 1/T \) slopes obtained as the high-temperature (\( T > 1000K \)) and low-temperature (\( T < 500K \)) straight-line extrapolations. It has not been, in the past decade, that curvature in the log \( k(T) \) vs. \( 1/T \) (so-called Arrhenius) plot is unacceptable; theoretically, curvature has been considered likely for some time. The lack of sufficient congruence of data in either (high or low) temperature regime and the nearly total absence of reliable rate constant data between 500K and 1000K has delayed until quite recently and limited to just a very few reactions even the empirical smooth joining of high and low temperature measurements.

It is precisely that void in elementary reaction rate constant measurements from 500-1000 K that has inspired the development and growth of this research program. Using our technique, we can obtain data in the intermediate temperature range, and also completely cover the low temperature regime of 220-500 K, thus providing one set of data which spans nearly a factor of five in \( 1/T \) values. During the second year of the program, rate coefficient measurements over extended temperature ranges, were made for the following reactions:

\[
\begin{align*}
\text{OH} + \text{H}_2 & \overset{k_1}{\longrightarrow} \text{H}_2\text{O} + \text{M} \\
\text{OH} + \text{CH}_4 & \overset{k_2}{\longrightarrow} \text{H}_2\text{O} + \text{CH}_3 \\
\text{OH} + \text{CO} & \overset{k_3}{\longrightarrow} \text{H} + \text{CO}_2 \\
\text{OH} + \text{C}_2\text{H}_6 & \overset{k_4}{\longrightarrow} \text{H}_2\text{O} + \text{C}_2\text{H}_5
\end{align*}
\]
Distinct curvature in the Arrhenius plot, varying in degree, was found for each Reaction (1)-(4) [2].

During the past year, this work has been expanded to the following reactions:

\[
\begin{align*}
\text{OH} + \text{D}_2 & \rightarrow \text{DHO} + \text{D} \\
\text{OH} + \text{HCl} & \rightarrow \text{H}_2\text{O} + \text{Cl} \\
\text{OH} + \text{C}_3\text{H}_8 & \rightarrow \text{H}_2\text{O} + \text{C}_3\text{H}_7
\end{align*}
\]

Again, distinct curvature in the Arrhenius plot has been observed for Reactions (6) and (7). Surprisingly, Reaction (5) seems to follow a nearly linear Arrhenius plot in the temperature range of 298-1000 K. Our results for Reaction (5) are listed in Table I and are plotted in Figure 1. Also shown in Figure 1 are the results of Smith and Zellner [3], the single reported study of Reaction (5); in this investigation covered a temperature range of 220-460 K. Our lower temperature results agree quite well with Smith and Zellner’s data in the temperature range overlapped by the two studies. Extrapolation of Smith and Zellner’s data to 1000K gives a value of \(k_5\) which is approximately 60% lower than our data suggests; this clearly is due to the slight curvature in the Arrhenius plot for Reaction (5).

Figure 2 shows Arrhenius plots for Reactions (1) and (5). It is clear from the plots that the Arrhenius plot for Reaction (5) is reasonably straight while that for Reaction (1) is curved! The explanation for this observation may be that H-atom tunneling is more pronounced in Reaction (1) than that of D-atom in (2). Alternatively, it may be due to the mass effect in the transition state complex. To better answer this question, we have extended the measurement of both \(k_1\) and \(k_5\) to lower temperatures, i.e., \(\sim 230K\). The data

analysis is currently underway and we should have the results in the next few weeks.

Absolute reaction rate coefficient measurements obtained for Reaction (6) are listed in Table II and are plotted in Figure 3. Also shown are the results of three low temperature investigations [3,4,5] of Reaction (6). It is clear that the low temperature results do not extrapolate well to high temperatures. Even the results of Smith and Zellner [3], which gave the largest activation energy, fall below our results. Of course, it should be noted, that our low temperature results are in excellent agreement with all three previous measurements. This curved Arrhenius plot for Reaction (6) suggests that HCl would react with OH faster (by \( \sim \) a factor of 2) at plume temperatures.

Experimental measurements of \( k_7(T) \) for Reaction (7) are listed in Table III and plotted in Figure 4. Prior to these measurements, the only reliable rate coefficients existing for this reaction were a few measurements at and slightly above room temperature. Once again, it can be seen from Figure 4 that straight-line extrapolation of low temperature measurements [6] results in an underestimation of the bimolecular rate constant \( k_7(T) \) at higher temperatures; concave upward curvature is again evident.

The value of these results (and of our developed experimental technique) is not limited to the numerical achievements detailed above. Typically, the complexity of the chemistry involved in a combustion and/or plume process is nearly overwhelming. In recent years it has become increasingly obvious that it is simply not possible to measure the kinetic parameters for all contributing elementary reactions in a complex process. Indeed, if such a data base did exist, computational limitations would prevent its full utilization. Increasing attention is thus being focused on the generation of 'global' kinetic

equations, i.e., kinetic expressions which are approximately applicable to families of analogous chemical reactions. Such a viewpoint then argues the need for investigations which emphasize the effects of chemical structure on the rates of reactivity; studies aimed at generating an improved understanding of the general temperature dependence of bimolecular reaction rates must be pursued. The results obtained in this program should be considered to represent some of the initial steps of this approach.

Utilizing the technique of flash photolysis-resonance fluorescence the rate constants for the reactions of hydroxyl radicals (OH) with deuterium, hydrogen chloride, and propane were measured at elevated temperatures as high as 1000K. Distinct curvature was observed in the Arrhenius plots for OH reactions with HCl and propane while the OH + D₂ reaction rate coefficient seemed to follow the Arrhenius law quite well. The measured rate constants were compared with previous measurements in the literature.

ABSTRACT

During the course of this program experimental investigations have been carried out to meet two objectives, a) to measure the temperature dependence of rate coefficients of radical-molecule and molecule-molecule reactions of specific importance in modeling of combustion and plume processes, and b) to contribute to the general understanding of the temperature dependence of bimolecular reactions, particularly as it relates to observed curvature in Arrhenius plots. The technique of flash photolysis-resonance fluorescence has been adapted to measure directly rate coefficients for OH reactions in the temperature range of 250-1100 K. Kinetic data for the important reactions of OH + M₂, D₂, CH₄, C₂H₆, C₃H₈, HCl, and CO was obtained. In addition, the general oxidative conversion of BCl₃ and BF₃ were also investigated.
INTRODUCTION

Aircraft and rocket exhaust plumes provide an energetic, highly non-uniform, local environment within which microscopic physical and chemical processes act to dictate the nature of bulk observations of the medium. Analyses of fuel performance and tracking procedures rely on modeling of those contributing processes which, in combination, govern the efficiency of the propulsion system or surveillance method under examination. Chemically, reactions within the combustor and afterburning within the plume place heavy demands on the estimating prowess of kinetic modellers. In most cases, it is simply not possible to calculate which among the myriad of possible processes are most important (and thus which among the possible molecular species are of greatest concern)—an extensive data base, promoting realistic modeling parameter limitations, is needed. From a kinetic standpoint, optimized acquisition of this data base implies the measurement of oxidant/fuel/reaction intermediate reaction rate constants needed directly for model input and/or required as bases for the generation of 'global' kinetic equations applicable to entire families of chemical reactions. Improvement of the understanding of those factors which govern the temperature dependence of combustor/plume relevant bimolecular reactions was the primary goal of this research program.

The results are presented in the following four Sections. Section I has been recently published in the Journal of Physical Chemistry. Section III will be submitted shortly to the Journal of Physical Chemistry for publication. It is anticipated the contents of Section IV would also be submitted for publication in the next few months.

INTRODUCTION

Experimental measurements of absolute rate constants for radical-molecule reactions have historically been divided according to temperature regime. At low temperature ($T \leq 500K$) a variety of techniques\textsuperscript{1} have been developed and utilized in recent years in response to the input demands of atmospheric chemical modeling. Generally speaking these techniques permit the adjustment of experimental conditions such that the absolute rate constant measurements for many specific radical-molecule reactions may be made with little, and/or quantifiable, interference from competing reaction processes. At high temperature ($T \geq 1000K$) kinetic isolation of a given reaction has proven to be much more difficult to achieve. Experiments at flame temperatures typically range from studies utilizing end product analysis alone to investigations involving detailed concentration mapping vs. time (distance) of a number of radical (stable molecule) species whose interactive chemistry is very complex. Sequences of reaction schemes with parametrized absolute rate constant values are used to iteratively reproduce the measured concentration profiles (product yields). Frequently the extracted rate constants are model-dependent, ratioed to those of another insufficiently characterized reaction, or sensitive within only broad limits on the obtained raw data. The interpretive clarity of high temperature kinetic measurements has been observed to parallel the level of experimental control.

At temperatures intermediate between these separated regimes, 500-1000K, relatively few investigations of radical-molecule reaction rate constants have been undertaken. Two reactions which have received some attention\textsuperscript{2,3} in this interval as well as extensive study at high and low temperatures are the subject of the present investigation:
Published kinetic data on Reaction (1) has recently been critically evaluated and summarized by Cohen and Westberg. Based principally on kinetic measurements made below 500K and above 1000K, these authors recommend a three-parameter rate constant expression of functional form 

\[ k(T) = AT^n \exp(-E_0/RT) \]

as an appropriate fit to the Arrhenius graph curvature experimentally defined for Reaction (1). Non-Arrhenius behavior is also evident in kinetic measurements made on Reaction (2). Zellner has used this same functional form to empirically effect a smooth joining of the low and high temperature rate constant measurements for this reaction.

In this paper we present the first in a series of studies of the reaction kinetics of the hydroxyl radical at intermediate temperatures. Using the direct kinetic technique of flash photolysis-resonance fluorescence absolute rate constants for Reactions (1) and (2) have been obtained up to temperatures of 1000K. These results will be described and compared with those of previous measurements and compilations.

EXPERIMENTAL SECTION

The application of the flash photolysis-resonance fluorescence technique to the study of OH radical reaction kinetics has been discussed previously. Hence we will describe the experimental apparatus briefly, emphasizing only those new features which for the first time extend the temperature range of applicability of the technique to above 1000K.

A schematic diagram of the experimental apparatus is shown in Figure 1. The principal components of this system are (1) a quartz
reaction cell resistively heated using electrically insulated tantalum wire windings mounted to its graphite-coated outer surface; (2) a spark discharge flashlamp perpendicular to one face of the cell; (3) a CW OH resonance lamp perpendicular to the photolysis beam; (4) a photomultiplier/bandpass filter combination for monitoring OH resonance fluorescence perpendicular to both the photolysis and resonance radiation beams; and (5) a signal averager and fast photon counting electronics.

The present experiments were carried out using a static reactor configuration. Typical gas mixtures consisting of 150 mtorr H₂O, 0-1 torr (CH₄), and 50 Torr argon were flash photolyzed thereby initiating the primary reaction sequence

\[
\begin{align*}
H₂O & \overset{h\nu}{\longrightarrow} H + OH(X^2\pi) \\
165 \text{ nm} & < \lambda < 185 \text{ nm} \\
OH + H₂(CH₄) & \overset{k_{bi}}{\longrightarrow} H₂O + H(CH₃).
\end{align*}
\]

It is worth noting here that our use of Suprasil quartz optics with a transmission cutoff at 165 nm prevented photolysis of H₂ and CH₄ and thus eliminated a major potential source of unwanted radicals and competing radical-radical reaction processes. Following the flash weakly focused resonance lamp radiation continuously excited a small fraction of the OH to the A²Σ⁺ state and the resultant (0,0) band fluorescence was counted in real time; the temporal profile of OH decay was constructed by signal averaging over a large number of flashes for each fixed reactant concentration. The reactant concentrations [H₂] and [CH₄] were maintained at large excess over [OH] ([OH]₀ = 1-5 x 10¹¹ molec/cm³) and the reaction kinetics were thus pseudo first order in [OH]. Exponential [OH] decays (through several 1/e times) were obtained, their time constants yielding the first order rate constant for OH disappearance at the re-
actant concentration of that mixture. Bimolecular rate constants were obtained as the slope of a plot of the measured first order rate constant vs. reactant concentration ([H₂] or [CH₄]). System parameters such as flash energy, H₂O concentration and total pressure were varied to demonstrate the lack of importance of competing secondary processes in our measurements on Reactions (1) and (2). During the generation of most [OH] decay curves several cycles of reactor filling/evacuation with identical gas mixtures were used so as to negate the kinetically deleterious effects of reactant depletion and product buildup (within the exposure limits used the measured rate constants were shown to be independent of the number of flashes to which any gas filling was subjected).

The two principal experimental factors which have permitted direct measurements of absolute rate constants to be made at temperatures in excess of 1000K involve the system optics configuration and the reaction cell design. Collimation and weak focusing of the incoming flashlamp and resonance lamp radiation and of the emitted fluorescence have been employed and have resulted in an OH detection sensitivity which is significantly enhanced relative to that available in previous high-pressure studies of Reactions (1) and (2). A detailed discussion of the detection sensitivity characteristics of a completely analogous experimental configuration is contained in a recent publication describing our laboratory's study of the OH + NO₂ + M → HNO₃ + M reaction. Highly polished Suprasil windows have been fused using quartz tape to an all quartz body to form the high-temperature reactor. Efficient heating and radiation shielding maintain a higher temperature at the body of the reactor than that at the protruding windows, the reaction temperature being measured by both internal (insertable) and external (body-
mounted) Chromel-Alumel thermocouples. During the period of measurement of each individual bimolecular rate constant the reactor temperature was held constant to within ± 3 K by applying a controlled constant voltage to the resistive heaters. The temperature profile along the axis of the cylindrical reactor was measured using the retractable thermocouple at pressure conditions identical to those existing during kinetic measurements. The temperature differential between the upper and lower portions of the reaction zone (maximum length ~ 2 cm) was found to be ≤ 5 K at a reactor temperature of 1000 K. The bottom window (fluorescence port) temperature was measured to be ≈ 25 K below that of the reaction zone at 1000 K; given the heater and radiation shield positions and the overall reactor geometry, side window temperatures are estimated to be comparable to that measured at the bottom window. Considering the relatively large reactor diameter used in this work (reactor volume ~ 500 cm³), such temperature gradients are likely to be only a minimal source of experimental error.

Figure 2 shows typical OH decay profiles at three temperatures. These decay rates were all measured using the same diluent gas pressure, H₂O pressure, and photolysis flux. The high temperature experiments required longer periods of signal averaging than the lower temperature measurements; for example, twice as many flashes were needed at 1020 K than at 619 K to produce a good quality decay curve. At an H₂O partial pressure of ~ 150 mTorr the fluorescence signal strength as a function of temperature was seen to scale closely with H₂O number density indicating minimal temperature dependent optics transmission effects; repeated temperature cycling of the reactor did, however, induce long-term degradation of the vacuum-UV transmission efficiency of the Suprasil windows.
[The static reactor used in the present work has since been replaced by an analogous "slow flow" high-temperature quartz reaction cell which transmits a continuously controlled flow of mixture of desired composition and thereby permits each initiating flash to encounter a "locally fresh" reaction mixture.]

The gases used in this study were obtained from Matheson Co. and had stated minimum purities as follows: $\text{H}_2$, 99.9999%; $\text{CH}_4$, 99.99%; and Ar, 99.9995%. Prior to their use, hydrogen and methane were passed through a trap at 77K to remove residual condensibles.

RESULTS AND DISCUSSION

The bimolecular reaction rate constants obtained in this study were generated from measurements of hydroxyl radical decay rates at several fixed reactant concentrations for each temperature. Plots of the first order decay constant vs. reactant concentration at selected temperatures between 499-1020 K are given for Reactions (1) and (2) in Figures 3 and 4, respectively. The bimolecular rate constants obtained as the slopes of the included least-square lines are listed with $\pm 2\sigma$ precision limits in Tables I and II. Room temperature rate constant values obtained in this work are in good agreement with those of previous studies tabulated in the data evaluations of References 4 and 5.

The major potential sources of systematic error in the measured values of $k_1$ and $k_2$ are the uncertainties in the reactant concentrations and in the temperature. At 298K the reactant concentrations of source mixtures could be determined quite accurately ($\% 3\%)$ using a capacitance manometer since both $\text{H}_2$ and $\text{CH}_4$ are non-sticky and non-condensable compounds. Reaction fillings were made using these calibrated source mixtures and elevated temperature reactant concentrations were calculated by scal-
ing accordingly to source mixture content and temperature. Including errors due to temperature uncertainties, then, the estimated error in reactant concentrations was $\leq 10\%$. Thus we estimate that the accuracies (95% confidence limit) of the measured values of $k_1$ and $k_2$ are $\approx 13\%$ at 298K increasing to $\approx 20\%$ at 1000K.

Our data for $k_1(T)$ are plotted along with selected previous results and analytical evaluations in Arrhenius graph form, $\ln k(T)$ vs. $1000/T$, in Figure 5. Our results cover a sufficiently wide temperature range to independently demonstrate the existence of curvature in the Arrhenius plot for Reaction (1). At low and relatively high temperature our measurements are in excellent agreement with the rate constant values calculated from Cohen and Westberg's summary expression

$$k_1(T) = 1.83 \times 10^{-16} \ T^{1.3} \ \exp(-1835/T) \ \text{cm}^3\text{molec}^{-1}\text{sec}^{-1}.$$  

In the interval 499-648 K, however, measurements made in the present study fall about 20% below those derived from this $k_1(T)$ expression. Similarly, in the only previously published direct kinetic study of Reaction (1) at intermediate temperatures, Westenberg and deHaas measured $k_1$ values between 403-745 K which averaged 22% below those calculated from the Cohen and Westberg formula. Interestingly Cohen and Westberg did not weight data at intermediate temperatures heavily in their evaluation; indeed, hardly any measurements between 500-1000 K were available. While our measurements yield generally very good agreement with the $k_1(T)$ values calculated from Cohen and Westberg's expression, they do suggest somewhat more pronounced Arrhenius graph curvature than that expression describes. The best fit expression calculated from our data only is $k_1(T) = 4.12 \times 10^{-19} \ T^{2.44} \ \exp(-1281/T) \ \text{cm}^3\text{molec}^{-1}\text{sec}^{-1}$. Zellner's suggested expression of $k_1(T) = 1.66 \times 10^{-16} \ T^{1.6} \ \exp(-1660/T) \ \text{cm}^3\text{molec}^{-1}\text{sec}^{-1}$ is perhaps the most appropriate fit to all available data. [With regard to curvature in Arrhenius plots it is of interest to note that preliminary
results of our OH + D2 + DHO + D study\textsuperscript{10} between 298-932 K demonstrate markedly less Arrhenius graph curvature than that found to be appropriate for Reaction (1).]

Our rate constant measurements for the OH + CH\textsubscript{4}, \textit{k\textsubscript{2}}, H\textsubscript{2}O + CH\textsubscript{3} (2) reaction are plotted along with selected previous work in Arrhenius graph form in Figure 6. Once again our data clearly demonstrates the existence of pronounced Arrhenius graph curvature for Reaction (2). Immediately apparent from this figure is the fact that straight-line extrapolations of either the low-temperature based NASA recommendation\textsuperscript{11} or the high-temperature based Peeters and Mahnen recommendation\textsuperscript{12} produce order of magnitude errors in \textit{k\textsubscript{2}(T)} in the opposite temperature regime. Based principally on low- and high-temperature experimental measurements, Zellner\textsuperscript{5} derived an empirical best fit for \textit{k\textsubscript{2}(T)} given by \textit{k\textsubscript{2}(T)} = 2.57 \times 10^{-18} T^{2/3} \exp(-1233/T) \text{cm\textsuperscript{3}molecule\textsuperscript{-1}sec\textsuperscript{-1}}. Within experimental error both our data (298-1020 K) and the single point of Ernst, Wagner and Zellner (1300k)\textsuperscript{13} fall dead-on the curve (solid line in Figure 6) traced out by this expression. Interestingly, the calculated best fit expression based on our data only, \textit{k\textsubscript{2}(T)} = 1.32 \times 10^{-17} T^{1/2} \exp(-1355/T) \text{cm\textsuperscript{3}molec\textsuperscript{-1}sec\textsuperscript{-1}}, yields a curve which is barely distinguishable from that recommended by Zellner. Indeed, given the quoted accuracies of these and previous measurements on Reaction (2), a rather extended array of parameters could be suggested as producing representative fits for \textit{k\textsubscript{2}(T)}. While the present experiments have demonstrated both the appropriateness of the functional form \textit{k(T)} = AT\textsuperscript{N} \exp(-Eo/RT) and the basic soundness of previous measurements in each separated temperature regime, the curve fitting calculations indicate that extreme caution must be exercised when attaching physical significance to multi-parameterized rate constant expressions.
At intermediate temperatures only one prior direct kinetic investigation of Reaction (2) has been undertaken. Using the technique of flash photolysis-resonance absorption, Zellner and Steinert\(^3\) measured \(k_2(T)\) up to temperatures of 892K. At lower temperatures these data agree well with Zellner's empirical fit, but at higher temperatures their measured \(k_2(T)\) values exceed the best fit values by a factor increasing with temperature and already more than two at 892K.

One possible explanation for the discrepancy at higher temperatures between Zellner and Steinert's results and those of the present study relates to the magnitude of the hydroxyl radical reactant concentration demanded by the resonance absorption and fluorescence detection modes. Although both techniques measure the disappearance of OH radicals in real time, the absorption technique monitors the difference between two large numbers \([(I_{t=0} - I_t)/I_{t=0}]\) and thereby requires much larger OH concentrations to match the statistics obtainable from the fluorescence technique. Thus Zellner and Steinert's initial post-flash OH concentrations were 40-100 times higher and their \([\text{CH}_4]/[\text{OH}]_{t=0}\) ratios were ~10 times lower than those characteristic of the present study. Such larger radical concentrations and lower reactant ratios enhance the probability of OH disappearance due to processes other than Reaction (2) and make more difficult kinetic isolation of this subject reaction. Based on sensitivity considerations, then, it appears that the fluorescence detection technique is best suited to the investigation of intermediate temperature hydroxyl radical reaction kinetics; indeed, it is the authors' opinion that present constraints on the general applicability of the flash photolysis-resonance fluorescence technique to combustion regime kinetics of O, H, and OH relate more to maintenance of the mechanical and optical
integrity of the experimental system than to limitations in detection sensitivity.

The experiments described above represent the first use of the flash photolysis-resonance fluorescence technique in the study of radical-molecule reaction kinetics above 500K. The need for direct kinetic investigations of prototype radical-molecule reactions from low temperatures to those well within the flame region is indisputable. Combustion modeling requires voluminous rate constant input from both direct measurement and extrapolation [note here the improvement in extrapolative accuracy achievable upon progression of data availability limits from 400K (1000/T = 2.5) to 1000K (1000/T = 1.0)]. Enhancement of our general understanding of bimolecular reaction rate theory is ultimately required to render practical the global kinetic approach to the chemical modeling of complex systems. Unambiguous rate constant studies over wide temperature ranges (0.5 ≤ 1000/T ≤ 5.0) will promote this goal.

II. OXIDANT-HALOCARBON STUDIES
The achievement of an understanding of the oxidation characteristics of halogenated boron species is essential to the estimation of the concentrations of boron molecular emitters present in advanced fuel rocket plume exhausts. Knowledge of the typical concentrations of emitting species is a prerequisite to the interpretation of rocket plume infrared signatures. Since very little is known about haloborane oxidation (and also about the technology required for its study), we have studied relevant molecular reactions with the aim of aiding development of experimental techniques which would permit future investigation of the more complex radical reactive systems.

In the work statement for this program we were contracted to measure absolute rate constants for Reactions (1) and (2),

\[ \text{O}_2 + \text{BF}_3 \rightarrow \text{Products} \]  \hspace{1cm} (1)

\[ \text{O}_2 + \text{BCl}_3 \rightarrow \text{Products}, \]  \hspace{1cm} (2)

using the technique of stop-flow time-of-flight mass spectrometry. A schematic diagram of this technique is displayed in Figure 1. In this system a thermostated reaction vessel equipped with a very small molecular leak is positioned directly above the ion source of a time-of-flight mass spectrometer. Reactants are admitted to the vessel and mix homogeneously and reach temperature equilibrium within a few milliseconds. Following mixing, the reaction is occurring at the desired conditions of temperature, pressure and reactor composition. The molecular leak at the bottom of the reaction cell allows a very small fraction of the cell contents to diffuse into the ion source of the mass spectrometer. This effluent is ionized, the ions are accelerated to constant energy, and the ion current and time of
Figure 1. Stop-Flow Time-of-Flight Mass Spectrometer System.
arrival at the detector are measured. The entire spectrum can be cycled every 100 μsec. In essence, this technique allows the determination of the cell contents in real time. In a kinetic experiment, however, only one ion, produced upon ionization of either a reactant or product molecule, is monitored with time. The temperature range of our stop-flow system is 250K-450K. Second order reaction rate constants between $2 \times 10^{-23}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ and $5 \times 10^{-17}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ are amenable to accurate measurement within this system. Since this range of rate coefficients corresponds to that expected for many molecule-molecule reactions, this technique was proposed for the study of Reactions (1) and (2).

When stop-flow time-of-flight mass spectrometry experiments were performed on Reactions (1) and (2), it was found that within experimental error addition of one reactant to the reaction vessel had no effect on the rate of disappearance of the other reactant. We thus estimated that the rate constants for these processes are $\leq 1 \times 10^{-23}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.

Having found that the rate constants for Reactions (1) and (2) are too slow to be measured by the above technique, we devised a time-resolved infrared spectroscopy study of these reactions. An optical absorption cell seasoned with the haloborane prior to each experiment was filled with a few torr of the haloborane and 350-500 torr of oxygen. Haloborane infrared absorption intensities were then monitored as functions of time. Typical results of these experiments are plotted in Figure 2. The haloborane decay rates are seen to be extremely slow and, because wall loss effects may have been contributing to the observed decays, the rate constants extracted from these pseudo-first order decays must be considered as upper limits. Our knowledge of these rate constants thus remains limited to the expressions $k_1 \leq 1 \times 10^{-30}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ and $k_2 \leq 4 \times 10^{-25}$ cm$^3$ molecule$^{-1}$ s$^{-1}$.
Figure 2. Time-Resolved Infrared Spectroscopy.

\[ P_{BCl_3}^0 = 1.1 \text{ Torr}; \ P_{O_2}^0 = 380 \text{ Torr} \]

SLOPE \( k' = 4.89 \times 10^{-6} \text{ sec}^{-1} \)

\( k_{b1} \leq 4 \times 10^{-25} \text{ cm}^3/\text{molec} \cdot \text{sec} \)

\[ P_{BF_3}^0 = 2.3 \text{ Torr}; \ P_{O_2}^0 = 460 \text{ Torr} \]
Having observed nearly negligible reactivities for the reactions $O_2 + BF_3/BCl_3$, we decided to probe the general oxidative behavior of the haloboranes in more detail by studying their reactions with more active oxidizing agents. Investigations of the following reaction processes were made:

\[ O_3 + BF_3 \rightarrow \text{Products} \quad (3) \]

\[ O_3 + BCl_3 \rightarrow \text{Products} \quad (4) \]

\[ H_2O + BCl_3 \rightarrow \text{Products} \quad (5) \]

Again using the technique of time-resolved infrared spectroscopy, Reaction (3) was investigated and found to be immeasurably slow at room temperature. This reaction, then, was not looked at further. The study of Reaction (4), on the other hand, proved to be very interesting. Time-sequenced sets of complete infrared spectra of reacting $O_3/BCl_3/Ar$ mixtures were taken. The initial $BCl_3$ and argon pressures were measured using a capacitance manometer and the initial $O_3$ pressure was calculated from UV absorption measurements made at 254 nm. The initial reactant partial pressures were varied by as much as factors of four in different runs. The $BCl_3$ and $O_3$ decay rates and reaction product buildup rate (as shown in Figure 3a, a reaction product peak not observed in the pure $O_3$ or pure $BCl_3$ spectra grows with time) are calculated from the peak intensities in the sequential infrared spectra. Relative concentration vs. time after mixing plots for a typical experimental run are displayed in Figure 3b. It is seen that the rate of growth of the reaction product closely images the rate of decay of the $BCl_3$ reactant. It is worth noting here, however, that the bimolecular rate constants calculated from such plots do show a slight tendency to increase with increasing $[O_3]_{t=0}/[BCl_3]_{t=0}$ ratios. These variations are likely due to the overall stoichiometry of the reaction.

Figure 3b. First Order Decay Plot for the Disappearance of BCl₃ and Appearance of Reaction Product in the Reaction of BCl₃ with 0₃: [O₃] > [BCl₃].
Three other experimental techniques were applied to the study of Reaction (4): (1) time-resolved UV absorption spectroscopy, (2) stop-flow time-of-flight mass spectrometry, and (3) reaction end product analysis. The results of these studies will be discussed below in turn.

A schematic of the simple but very powerful technique of time-resolved UV absorption spectroscopy is given in Figure 4a. Light from a mercury lamp at 253.7 nm was passed through an absorption cell containing the O₃BCl₃/Ar mixture. The transmitted intensity was monitored as a function of time by a filtered photodiode. Experiments were run with [BCl₃] in varying excesses over [O₃], ozone being the monitored species. Use of this technique required considerable caution. Since 253.7 nm radiation is absorbed by ozone via the photodissociative reaction \( O_3 \rightarrow 0(1D) + O_2 \), the possibility existed that the atomic oxygen formed in the probe process could contribute to the chemistry under study. By using a variety of ozone concentrations and 253.7 nm radiation fluxes, however, it was conclusively shown that such probe-induced processes were unimportant. Furthermore, by allowing the low concentration reactant ozone to undergo complete reaction and the measuring essentially no absorption of 253.7 nm radiation, it was clearly demonstrated that the products of the reaction were not absorbing the probe radiation and thereby biasing the kinetic results. Thus the time variation of the transmitted 253.7 nm intensity generates an accurate time history of the ozone concentration.

The experiments were run under pseudo-first order conditions with BCl₃ in excess and, as shown in Figure 4b, the bimolecular rate constant was obtained as the slope of a plot of the pseudo-first order decay constant vs. the BCl₃ concentration. A value of \( k_{bi}(298K) = 8.31 \times 10^{-21} \text{ cm}^3\text{molecule}^{-1}\text{s}^{-1} \) was obtained.

Reaction (4) was also studied by the previously described technique of stop-flow time-of-flight mass spectrometry. Small concentrations of BCl₃
Figure 4a. Time-Resolved UV Absorption in $O_3 + BC_3$ Reaction.

Figure 4b. Plot of $O_3$ Decay Rate vs. $[BC_3]$. 

$$SLOPE = 2.66 \times 10^{-1} \text{ sec}^{-1} \text{ Torr}^{-1}$$

$$k = 0.31 \times 10^{-1} \text{ cm}^3/\text{molec-sec}$$
in varying excesses of ozone were mixed in the reaction vessel and the time
variation of the $\text{BCl}_2^+$ ion was followed mass spectrometrically. Typical decay
curves are shown in Figure 5a; a bimolecular rate constant of $k_{bi} = 1.2 \times 10^{-20}$
cm$^3$ molecule$^{-1}$ s$^{-1}$ was calculated by the usual methods. Averaging this result
with that obtained using time-resolved UV absorption spectroscopy techniques,
one obtains a room temperature rate constant for Reaction (4) of $k_{bi} =$
$(1.0 \pm 0.3) \times 10^{-20}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. It is worth noting here that this value
exceeds that obtained in the time-resolved infrared spectroscopy experiments
(see Figure 3) by about a factor of six. Though we do not feel that we can
adequately explain this discrepancy, it is probable that it is at least in
part related to wall absorption of ozone in the extended duration infrared
spectroscopy experiments.

Mass spectrometric studies of Reaction (4) were also performed by time
sequenced sweeps of the entire mass spectrum. From top to bottom, Figure 4b
shows respectively the mass spectrum obtained for pure ozone, that obtained
for pure $\text{BCl}_3$, and that obtained a substantial period of time after mixing
a small concentration of $\text{BCl}_3$ with a large excess of ozone. Close examination
reveals that the observed product patterns differ substantially from the
superposition of the pure O$_3$ and pure $\text{BCl}_3$ traces. In Table I we have listed
those significant mass peaks observed in the mixed O$_3$/BCl$_3$ system which were
found to be of only minor importance in either pure spectrum. Species such
as BO, BO$_2$, BC10, C1$_2$ and HCl have been identified. Other significant mass
peaks remain unassigned at this time.

Finally, an end product analysis investigation of Reaction (4) was
undertaken. Ozone and $\text{BCl}_3$ were mixed in a reaction vessel and allowed to
react to completion. The techniques of infrared and UV absorption spec-
troscopy and expansion of condensable and non-condensable gases into calibrated
volumes were utilized in the product analysis. As can be seen in Table II,

$$2 BCl_3 + 3O_3 \rightarrow BO_2 (?) + 3Cl_2 + 2O_2$$
$$B_2O_5 (?)$$
the loss of BCl$_3$ molecules was found to be about 2/3 that of the gain in Cl$_2$ molecules: chlorine balance seems assured through the formation of Cl$_2$. Since the number of condensable boron oxide molecules formed could not be measured, the boron and oxygen balances cannot be definitively assigned. One notices, however, that the loss of ozone molecules exceeds the loss of BCl$_3$ molecules, possibly by as much as a 3:2 ratio. If such stoichiometry is assumed, then the overall Reaction (4) mechanism could be represented by reaction expressions of the type (or linear combinations thereof) listed at the bottom of Table II.

An abbreviated stop-flow time-of-flight mass spectrometry study was also performed on Reaction (5). This reaction was found to be fast, probably heterogeneous, and produced HCl and condensable boron oxides in high yield. Indeed, the addition of pure BCl$_3$ to a reaction vessel which had previously contained H$_2$O resulted in both the fast decay of BCl$_3$ and the obvious formation of HCl. In experiments in which BCl$_3$ and H$_2$O were mixed in the gas phase, the molecular leak of the reaction vessel very quickly became clogged resulting in the termination of gas flow into the mass spectrometer analyzer.

The above described studies of Reactions (1) through (5) have resulted in some interesting information concerning the general oxidative behavior of the haloboranes. Equally important, they have provided sufficient knowledge to make possible studies of more plume-relevant processes such as the radical-molecule reaction

$$\text{O}(^{3}\text{P}) + \text{BF}_3/\text{BCl}_3 \rightarrow \text{Products}.$$
III. KINETIC STUDY OF THE REACTION OF OH WITH H₂ AND D₂ FROM 250 TO 1050 K
INTRODUCTION

The high temperature kinetic data needed for combustion modeling has been mainly derived from shock tube and flame studies. In these experiments, the accuracy of the obtained rate data is dependent on the degree of understanding of the chemistry involved in the system that is studied. In many cases it has been found that the extrapolation of the derived high temperature ($T > 1000K$) data to low temperatures ($T > 500K$) yield rate coefficients which disagree with the results of direct low temperature measurements. It has recently been recognized that this discrepancy could be due to either non-Arrhenius behavior\textsuperscript{1,2,3} of the reaction under study or to systematic errors in the high temperature data. To fully understand the variation of the rate coefficients with temperature in the intermediate temperature range, i.e., $298 > T > 1000K$, direct experimental measurements of elementary reaction rate coefficients are needed. This need has recently encouraged adaptation of proven low temperature kinetic technique to intermediate and high temperature studies. The developments have provided techniques which can directly measure the rate coefficient for an elementary reaction over a wide temperature range, thus minimizing the chances of relative systematic errors.

In parallel to these experimental developments, great strides have been made in theoretical calculations of elementary reaction rate coefficients.\textsuperscript{4,5} The transition state theory has evolved to a point where quite rigorous calculations of thermal rate coefficients can be carried out. This ability can be largely attributed to the availability of calculated \textit{(ab initio)} potential energy surfaces for many atom-diatom reactions and even four atom reactions such as OH + H\textsubscript{2}.\textsuperscript{6}

We have recently adapted the conventional technique of flash photolysis-resonance fluorescence to measure OH reaction rate coefficients at temperatures...
above 1000K.\textsuperscript{7,8} The rate coefficient for the reaction,

\begin{equation}
\text{OH} + \text{H}_2 \xrightleftharpoons[k_1]{k_2} \text{H}_2\text{O} + \text{H}
\end{equation}

was measured in the temperature range of 298-992K and the ln(k) vs. 1/T plot was found to be non-linear.\textsuperscript{7} Since our measurement of k\textsubscript{1}, an ab initio calculation of the potential energy surface for this reaction,\textsuperscript{6} as well as a transition state theory calculation\textsuperscript{5} of k\textsubscript{1} which utilized this surface, have been reported. The potential energy surface for the OH + H\textsubscript{2} reaction would be nearly identical to that of OH with D\textsubscript{2},

\begin{equation}
\text{OH} + \text{D}_2 \rightarrow \text{DHO} + \text{D}
\end{equation}

and therefore comparison of measured values of k\textsubscript{2} with those calculated would constitute a direct test of the theory. Also, the question of how isotopic substitution affects the curvature of Arrhenius plots is worth investigating. Therefore, with the hope of testing the theory and furthering our understanding of this elementary reaction, we have measured k\textsubscript{2} over the temperature range of 250-1050 K.

Even though both k\textsubscript{1} and k\textsubscript{2} have been measured by many investigators, they have not been studied using one direct technique which can cover a wide temperature range. As mentioned earlier, we have measured k\textsubscript{1} in the temperature range of 298 < T < 992 K. However, to obtain a consistent set of data for k\textsubscript{1} and also since k\textsubscript{1} has been measured only by one group at T < 298K,\textsuperscript{9} we extended the measurement of k\textsubscript{1} to 250K.

The technique of flash photolysis-resonance fluorescence as adapted for high temperature studies was utilized in carrying out all the reported measurements. A detailed description of this technique is given in this paper.
EXPERIMENTAL SECTION

The utilization of flash photolysis-resonance fluorescence (FP-RF) technique in studies of OH radical reactions at temperatures below 500K are amply described in the literature.\textsuperscript{10,11} We have recently adapted this technique for studies at temperatures up to \(\sim 1200K\). In this paper we will describe our high temperature system in detail.

The primary difficulty in using the FP-RF technique at high temperatures is maintaining good OH detection sensitivity while using a reactor which can be operated at these temperatures. We spent a considerable amount of time experimenting with various cell designs, cell materials, focusing optics, and light baffle arrangements to maximize OH detection sensitivity and still be able to heat the reactor to high temperatures. The final apparatus configuration that was adopted is shown in Figure 1. The principal system components are (1) a thermostated reaction cell, (2) a spark discharge flash-lamp perpendicular to one face of the cell, (3) a CW OH resonance lamp perpendicular to the photolysis beam, (4) a bandpass filter/photomultiplier combination for monitoring OH resonance fluorescence emitted perpendicular to both the photolysis and resonance radiation beams, and (5) a signal averager and fast photon counting electronics.

The reactor was built out of quartz. Five highly polished Suprasil windows were fused to the cell using quartz tape. This cell was coated with graphite on the outer surface. Once baked, the graphite bonded well with the quartz surface. This black graphite coating served two purposes: (1) it cut down the amount of scattered radiation, and (2) it formed a good thermally conductive surface which helped avoid 'hot spots'. This cell was heated using tantalum wire windings which were contained inside ceramic tubes. The heaters were powered by a constant voltage power supply. The temperature
could be controlled by changing the applied voltage using variacs. The
cell and the insulated heaters were covered with at least 5 layers of thin stain-
less steel sheets which acted as radiation shields, thereby minimizing the heat
loss from the cell. A chromel-alumel thermocouple was attached to the outer
surface of the reactor primarily to aid in knowing the temperature of the cell
during heating and cooling periods. The temperature of the gas inside the
reactor was directly measured using a thermocouple which was inserted
into the reactor. In preliminary characterization experiments the
temperature differential between the upper and lower portions of the
reaction zone (maximum length \( \sim 2 \) cm) was found to be \(< 5K\) at 1000K and
unmeasurable at 500K. The bottom window (fluorescence port located \( \sim 5 \) cm
below the active volume) was measured to be \( \sim 15K\) below that of the active
volume at 1000K when the gases were flowing through the cell. Therefore, it
can be quite confidently ascertained that at 1000K the temperature in the
active zone was constant to within 5K and known to better than 10K.

Quartz (unlike pyrex) transmits 310 nm radiation and thus increases the
background scattered resonance lamp radiation that reaches the detector. To
overcome this problem, two modifications were carried out. (a) The microwave
discharge lamp, the source of resonance radiation, was moved away (\( \sim 80 \) cm)
from the cell. A 5 cm diameter quartz convex lens was placed \( \sim 20 \) cm from
the discharge to collect the radiation and render it nearly parallel. A
second 5 cm diameter quartz lens located \( \sim 15 \) cm from the center of the
reactor, focused this parallel beam on the far port of the reactor. This
configuration enabled almost all resonance radiation to pass only through
the cell windows. (b) The photon counting electronics were improved to count
linearly up to 3 MHz. With this combination, the measured background count
rate ranged from 100-200 KHz. (It should be pointed out that generally
emphasis is placed on reducing the background rate to a very low value, often
at the expense of decreasing the amount of resonance radiation that enters the reactor.) The output of the \( N_2 \) flashlamp was collimated by a set of baffles and then rendered parallel by a pith polished Suprasil lens which ensured that all flash radiation exited only through the windows. In addition, a set of lenses was employed to collect the OH fluorescence from the center of the cell and then focus it onto the photocathode of a RCA 8850 photomultiplier tube. Use of this lens set resulted in increases in both fluorescence signal and background light with a large improvement in signal-to-noise ratio.

To determine the sensitivity of the apparatus, we carried out back-to-back experiments at 298K where the signal/noise per flash was determined under typical experimental conditions (flash energy = 70J, 50 mTorr \( H_2O \), 100 Torr Ar) and compared with the signal/noise per flash obtained under conditions where a known OH concentration could be produced. (Here, the signal/noise is defined as the ratio of signal due to OH to the square root of the background counts.)

The procedure used to generate a known concentration of OH involved replacing the flashlamp with a frequency quadrupled pulsed 266 nm laser beam (from a Nd: YAG laser) and adding \( \sim 5 \) mTorr \( O_3 \) to the reaction mixture. Upon photolysis the following reactions take place:

\[
O_3 \xrightarrow{h\nu \text{ 266 nm}} O(^1D) + O_2(^1\Delta_g) \\
\Downarrow \quad O(^3P) + O_2(^3\Sigma_g) \\
O(^1D) + Ar \rightarrow O(^3P) + Ar \\
O(^1D) + H_2O \rightarrow 2 \text{ OH}.
\]

The laser beam was expanded so its cross-sectional area as it traversed the reaction cell was approximately equal to that of the flashlamp radiation.

The laser power was measured at the rear of the cell with an absolute energy
monitor and corrected for the loss due to reflection by the back window
(\sim 10\%). Since the absorption cross section for \(O_3\) at 266 nm,\(^{12}\) the quantum
yield for \(O(1D)\) from \(O_3\) at 266 nm (\sim 0.9),\(^{13}\) the rate coefficients for \(O(1D)\)
quenching by Ar\(^{14}\) and reaction with \(H_2O\)\(^{15}\) are known, we could determine the
concentration of \(OH\) in the reactor.

The results of actinometry indicate that, for the reaction mixture
employed, \(\sim 1 \times 10^9\) \(OH\) per \(cm^3\) could be detected (signal/noise = 1) with an
integration time of \(1 \times 10^{-3}\) s. Extrapolation of this result to other experi-
mental conditions shows that all experiments were carried out with \(OH\) con-
centrations between \(1 \times 10^{10}\) and \(1 \times 10^{11}\) per \(cm^3\). It was also found that as
long as the reactor was kept clean, the measured signal for a given \(OH\) con-
centration did not deteriorate significantly with increases in temperature.

All experiments were carried out under pseudo-first order kinetic condi-
tions with \([H_2]\) and \([D_2]\) in large excess over \([OH]\). \([H_2]/[OH]\) and \([D_2]/[OH]\)
ratios were always greater than 1000. \([H_2]\) ranged from \(\sim 2 \times 10^{13}\) to \(2 \times 10^{17}\) \(cm^{-3}\)
and \([D_2]\) ranged from \(\sim 2 \times 10^{13}\) to \(1 \times 10^{18}\) \(cm^{-3}\). \(OH\) radicals were produced by
flash photolysis of \(H_2O\) at wavelengths between the Suprasil cutoff at 165 nm and
the onset of continuum absorption at 185 nm (flash duration \(\approx 50\) \(\mu sec\)).
Following the flash, weakly focused \(OH\) resonance lamp radiation continuously
excited a small fraction of the \(OH\) in the reactor to the electronically
excited \(A^2\Sigma^+\) state; the resultant \((0,0)\) band \(A \rightarrow X\) fluorescence emanating
in the direction perpendicular to both the resonance excitation and photolysis
beams was collected by a lens and focused onto a photomultiplier fitted with
a bandpass filter (309.5 nm peak transmission, 10 nm FWHM). Signals were
obtained by photon counting and then fed into a signal averager operated in
the multichannel scaling mode. For each decay rate measured, sufficient
flashes (50-1000) were averaged to construct a well-defined temporal profile over at least a factor of twenty variation in [OH].

All experiments were carried out under "slow flow" conditions. The flow rate through the reactor was such that each photolysis flash encountered a fresh reaction mixture (photolysis repetition rate $\sim 0.3$ Hz). At temperatures greater than 270K, H$_2$(D$_2$) was flowed from a 12k source bulb containing H$_2$(D$_2$)/diluent gas at 800 Torr through distilled water at room temperature. The H$_2$(D$_2$) diluent gas mixture, H$_2$O/diluent gas mixture, and additional diluent gas were mixed prior to entering the reaction cell. Concentration of each component in the reaction mixture was determined from measurements of the appropriate mass flow rates (measured using calibrated mass flow meters) and the total pressure. At temperatures below 270K, the amounts of H$_2$ and D$_2$ needed to carry out the experiments were so large that pure H$_2$ or D$_2$ was needed in the source bulb. Therefore, we prepared large amounts of H$_2$(D$_2$)/diluent mixtures in an $\sim 40k$ volume and flowed it directly into the reactor after mixing it with a small amount of H$_2$O/diluent mixture. This procedure avoided any possible flow meter calibration errors.

The gases used in this study had the following stated purities: Ar $> 99.9995\%$, H$_2$ $> 99.9999\%$, D$_2$ $> 99.96\%$. Also, the D$_2$ mixture had less than 1 ppm of organics (mainly as CH$_4$) and an isotopic purity of 99.5%. H$_2$ and D$_2$ were passed through liquid nitrogen traps filled with glass beads before being used to remove any condensible organics. Ar was used as supplied.

RESULTS

All experiments were carried out under pseudo-first order conditions with [H$_2$] or [D$_2$] $>>$ [OH]. The temporal profile of [OH], then, is given by the equation,

$$\ln\frac{[OH]_0}{[OH]_t} = (k_x[x] + k_d)t = k't$$
where $X$ is either $H_2$ or $D_2$, $k_d$ is the first order rate constant for the loss of $OH$ in the absence of $X$, and $k'$ is the measured pseudo-first order rate constant. [$OH$] decays were observed to be exponential for at least three $1/e$ times as typified by data shown in Figure 2; the exponential [$OH$] decay validates the existence of first order conditions. At each temperature, the [$OH$] decay rates were measured at several (minimum 4, on the average 6) fixed reactant concentrations. The bimolecular reaction rate constant was obtained from the slope of the $k'$ vs. reactant concentration plots. Figure 3 shows one such plot for $k_2$ at 932K. The measured values of $k_1$ and $k_2$ at various temperatures are listed in Tables I and II, respectively. The quoted errors are $2\sigma$ and represent the precision of the measured rate coefficient. It is estimated that the accuracy at 298K is $\sim 12\%$ decreasing to $\sim 20\%$ as the temperature is either raised to 1000K or lowered to 250K.

It has been previously shown that under our experimental conditions radical-radical reactions such as $H + OH$ or $OH + OH$ are insignificant.\textsuperscript{11} To ensure that our present results were devoid of such secondary reactions the [$OH$]$_0$, the flash energy, the [$H_2O$], and the system pressure, were varied at most temperatures. The results indicated the absence of any secondary reactions contributing to the measured value of $k_1$ and $k_2$.

The values of $k_1$ and $k_2$ are quite small at low temperatures. Therefore, very small concentrations of reactive impurities, in the order of $10^{-4}\%$, can contribute significantly to the measured values if they are present. It is always very hard to completely rule out this possibility of impurity reactions. Our samples of $H_2$ and $D_2$ are very pure. Both $H_2$ and $D_2$ have less than 1 ppm of $CH_4$, the only organic that was present in measurable quantities. Great care was taken to ensure that no impurities were added in the course of transferring $H_2$ and $D_2$ from the tanks to the reactor. Therefore we believe that our values of $k_1$ and $k_2$ are accurate to at least 20% at 250K.
Figure 4 shows plots of $\ln k_1$ and $\ln k_2$ vs. $1/T$. Results of our previous measurements of $k_1$ in the temperature range of 298 to 1000 K are also included. It is clear that Arrhenius plots are not linear for both $k_1$ and $k_2$; $\ln k_2$ vs. $1/T$ being more nearly linear than $\ln k_1$ vs. $1/T$. We previously fit $k_1$ values between 298K-1000K to the function $k(T) = 4.12 \times 10^{-19} \frac{1}{T^{2.44}} \exp(-1281/T)$ while Zellner obtained $k(T) = 1.66 \times 10^{-16} T^{1.6} \exp(-1660/T)$ based on all previous measurements. Our present data is best described by the former of the two expressions. A similar three-parameter expression for Reaction (2) based solely on our data is, $k_2(T) = 4.37 \times 10^{-15} T^{1.18} \exp(-2332/T)$.
DISCUSSION

Reaction (1) has been studied by numerous investigators\textsuperscript{16,17,18,19} at room temperature. There are four studies of $k_1$ as a function of temperature.\textsuperscript{9,20,21,22} With the exception of Westenberg and deHaas,\textsuperscript{21} all previous studies had an upper temperature limit of 500K. Table III lists both the 298K value and, where appropriate, the Arrhenius parameters. There is reasonable agreement between various $k_1$ (298K) values. As pointed out earlier the ln$k_1$ vs. $1/T$ (Arrhenius) plot is not linear. For the sake of comparison we have fitted our low temperature ($T < 400K$) data to an Arrhenius expression which yields:

$$k(T) = (4.9 \pm 0.5) \times 10^{-12} \exp\left[(1.99 \pm 0.34) \times 10^3 / T\right] \text{cm}^3 \text{molecule}^{-1} \text{s}^{-1}$$

where the errors are 2σ and $\sigma_A = \sigma_n A$. These values are listed in Table III. Our value of $A$ and $E/R$ are in good agreement with other measurements except with Smith and Zellner's values. Smith and Zellner\textsuperscript{9} were the only investigators who have measured $k_1$ at $T < 298K$. They encountered some difficulty at temperatures below 270K where they had secondary reactions such as

$$\text{OH} + \text{OH} + \text{M} \rightarrow \text{H}_2\text{O}_2 + \text{M} \quad (6)$$

and

$$\text{OH} + \text{H} + \text{M} \rightarrow \text{H}_2\text{O} + \text{M} \quad (7)$$

Contributing to the measured OH temporal profile. They corrected their measured value to take into consideration the contributions of these secondary reactions. The value of $2k_6 + k_7$ they used to correct their data was $\approx 7 \times 10^{-30} \text{cm}^6 \text{molecule}^{-2} \text{s}^{-1}$ which in the light of recent measurements\textsuperscript{23} seems rather high. Therefore it can be postulated that they over corrected their low temperature value which could account for the larger E/R values. Figure 4 shows the Arrhenius plots reported by Greiner,\textsuperscript{20}
Smith and Zellner, and Atkinson et al. It is clear from Figure 4 that our individual data points at $T \leq 298K$ are in excellent agreement with the line of Smith and Zellner. It is, however, our data $T > 298K$ which are lower than that of Smith and Zellner's line. Therefore it is doubtful that the low temperature corrections of Smith and Zellner could account for the discrepancy. Also, at $T > 298K$, the results of Westenberg and deHaas, Atkinson et al., and Greiner are all in good agreement with our values of $k_1$. It is particularly interesting to note the agreement over the entire temperature range of our results with that of Westenberg and deHaas who were the first to notice the non-linear variation of $\ln k_1$ with $1/T$.

Reaction (2) has been measured by three separate groups all at 298K. The temperature dependence of $k_2$ has been studied only by Smith and Zellner. Table IV lists all available data on Reaction (2). Again for the sake of comparison, we have fit our low temperature data to an Arrhenius form and obtained $A$ and $E/R$ which are shown in Table IV. There is reasonable agreement between all measured values of $k_2$ (298K); our value being the lowest. Even the Arrhenius parameters derived in this study based on low temperature (i.e. $T < 470K$) data, $k_2(T) = (1.21 \pm 0.52) \times 10^{-12} \exp\{(-2.67 \pm .15) \times 10^3/T\} \text{cm}^3\text{molecule}^{-1}\text{s}^{-1}$ agree well with that of Smith and Zellner.

One of the main aims of this work was to obtain a set of data using a single technique over a wide temperature range for a set of related reactions such that a coherent data base will be available to compare present day theory with experimental results. Based on our data two observations can be made. (a) The $\ln k$ vs. $1/T$ plots are not linear for both Reactions (1) and (2). (b) The kinetic isotopic effect, i.e., $k_1/k_2$ increases with decreases in temperature. Comparison of experimental results with theory can be made at different levels of quantification. The general non-linear Arrhenius behavior for reactions such as Reactions (1) and (2) can be qualitatively explained, and is even to be
expected, based on chemical kinetic theories of elementary reactions. Zellner and Gardiner have discussed the probable causes for this behavior which can be understood to different levels of precision based on the transition state theory and/or the collision theory.

Before comparing the theoretical calculations with experimental results, the mechanism for the reaction of OH with hydrogen needs to be explicitly stated. This reaction seems to proceed through the bond scission in hydrogen,

\[
H_aO + H_b \rightarrow H_b - H_aOH \rightarrow H_a + H_b
\]

rather than the O-H bond cleavage

\[
H_aO + H_b \rightarrow H_b - O - H_b + H_a
\]

This assumption is made in all calculations and is seldom stated explicitly. There is evidence to justify this mechanism based on the work of Westenberg and deHaas who observed the almost exclusive production of H atoms in the reaction of OD with H\textsubscript{2} (rather than D atoms which would be produced if the bond in hydroxyl radical was cleaved) and the work of Paraskevopoulos and Nip, who noted the absence of kinetic isotopic effect between the reaction of OH with H\textsubscript{2} and OD with H\textsubscript{2}.

The transition state theory can be used at many levels of rigor to calculate the value of \( k_1(T) \) and \( k_2(T) \) (and hence \( K_1(T)/k_2(T) \)). Assuming a transition state structure one can predict the temperature variation of the bimolecular rate coefficient \( k \), especially when the transition state properties are made to fit the value of \( k \) measured at one temperature. Recently, however, ab initio potential energy surfaces have been calculated for simple atom-diatom reactions and even four atom reactions such as Reactions (1) and (2). Using this potential energy surface, conventional transition state theory calculations have been carried out by Schatz and Walch and Isaacson and Truhlar for Reaction (1) and by Schatz and Wagner and Isaacson and Truhlar for Reaction (2). Isaacson and Truhlar have also calculated \( k_1(T) \) and \( k_2(T) \) based on canonical
variation theory. Figures (5) and (6) show the calculated values of $k_1(T)$ and $k_2(T)$, respectively, based on conventional transition state theory which includes and excludes tunneling as well as the canonical variation theory which excludes tunneling. Two points are clear: (a) calculated $k_1(T)$ values are much lower than experimental values when tunneling is neglected, the discrepancy between calculated and experimental values increasing with decreasing temperature, and (b) the $k_2(T)$ values which are calculated on the same potential energy surface as that for Reaction (1) and which includes tunneling correction, predicts $k_2(T)$ values much lower than measured values. The fact that the calculated rate coefficients are very sensitive to the exact choice of input parameters is seen when we compare the results of Schatz and Walch with those of Isaacson and Truhlar. Using the same potential energy surface, they obtain different results which are directly attributed to differences in partition functions, and the incorporation of anharmonicity, spin orbit coupling, etc. The canonical variation theory calculations which exclude tunneling yield the lowest calculated values for both $k_1(T)$ and $k_2(T)$. In fact, the difference between the calculated and measured values of $k_1(T)$ at 250K is \( \sim \) a factor of 20. However, it is expected that inclusion of tunneling would greatly enhance the agreement between calculations and experimental results. It should be noted that all these calculations suggest that tunneling is a major contributor to the overall rate coefficient for the reaction and the tunneling contribution increases quite dramatically with decreases in temperature.

Another experimental parameter which can be compared with theoretical calculations is the kinetic isotope effect, i.e., $k_1/k_2$. Table V lists these values for all the cases considered above as well as the calculations of Smith and Zellner. Smith and Zellner used two different semiempirical surfaces,
i.e., LEPS and BEBQ, and they neglected tunneling. It should also be noted that they assumed the energy barrier height to be the same as the experimentally measured activation energy. It is clearly seen that all calculations show the observed trend in \( k_1/k_2 \), i.e., decrease with increase in temperature. Moreover, it is interesting to see that the best agreement between measured and calculated values of \( k_1/k_2 \) is obtained when tunneling is neglected. Even in the case of the semiempirical calculation of Smith and Zellner, there is good agreement between measured and calculated kinetic isotope effects. In fact, this surprising agreement led to the speculation that tunneling is probably not important in Reactions (1) and (2). However, in spite of the good agreement in isotope effect ratios, the absolute values of \( k_1 \) and \( k_2 \) are grossly underestimated when tunneling is neglected as shown by calculations of Schatz et al.\(^5\),\(^27\) and Truhlar et al.\(^26\).

At this point one is forced to ask the question, even if an accurate ab initio potential energy surface is available, can the present theories accurately predict thermal rate coefficients, and, can the theories shed more light on the exact nature of the reactive process. Based on the calculations that are presented it is seen that even though great strides have been made in this direction, the theory still needs to be refined to predict rate coefficients with the accuracy of 10-50\%. Of course, it should always be kept in mind that ultimately the agreement between theory and experiment is a reflection on the accuracy of the potential energy surface itself.

The explanation of the non-Arrhenius behavior of \( k_1 \) and \( k_2 \) based on the collision theory has been discussed by Zellner\(^2\) and Gardiner.\(^3\) As pointed out by Zellner,\(^2\) if the rate coefficient for the reaction of OH\((v=1)\) with \( \text{H}_2 \) is \( \sim 150 \) times that for \( \text{H}_2 \,(v=0) \), then depending on the efficiency with which the increased vibrational energy can help hasten the reaction, the observed
thermal rate coefficient can exhibit different degrees of non-Arrhenius curvature. Zellner et al.\textsuperscript{28} have observed that H\textsubscript{2}(v=1) is removed by OH with a rate coefficient of \( \sim 1 \times 10^{-12} \text{ cm}^3\text{molecule}^{-1}\text{s}^{-1} \). If this removal is attributed totally to reaction rather than vibrational relaxation, a possibility that is not experimentally proven, then H\textsubscript{2}(v=1) can contribute significantly to \( k_1(T) \) even at temperatures as low as 800K. Of course, this mechanism does not preclude contribution due to tunneling at low temperatures. In the absence of any data on D\textsubscript{2}(v=1) it is hard to speculate if such a process can contribute to \( k_2 \). It should be noted that the population of D\textsubscript{2} in v=1 would be much higher than that of H\textsubscript{2} and if D\textsubscript{2}(v=1) reacts as fast as H\textsubscript{2}(v=1) is postulated to do, the contribution of D\textsubscript{2}(v=1) can be more than that of D\textsubscript{2}(v=0) at temperatures as low as 900K, and hence would be easier to measure.

Finally, it is worth inquiring what experimental work can be carried out to further check and aid in the development of the theories of elementary reactions. Two experiments are suggested, (a) extension of measurement of \( k_1 \) and \( k_2 \) to temperatures much lower than 250K where tunneling should dominate and temperatures higher than 1000K where energetics are less important and (b) measure rate coefficients for the reaction of OH with HD. Since the same potential energy surface that is used for H\textsubscript{2} and D\textsubscript{2} will be applicable, it will be interesting to see if the theory can predict the measured thermal rate coefficients for the reaction of OH with HD. Both these experiments will be underway shortly in our laboratory.

IV. KINETICS OF THE OH REACTIONS WITH CO, HCl, C₂H₆ AND C₃H₈
The reaction of hydroxyl radicals with CO,

\[ \text{OH} + \text{CO} \rightarrow \text{CO}_2 + \text{H} \] (1)

is of extreme importance in combustion and atmospheric processes. In combustion systems, Reaction (1) is the principal mode of conversion of CO to CO\(_2\). Since this reaction is very exothermic, its kinetics considerably impact the time profile for combustive energy release, and thereby, factors such as ignition, acceleration and propagation of flames. Also, in the atmosphere, Reaction (1) is the principal CO \(\rightarrow\) CO\(_2\) conversion pathway; its kinetics thus impact numerous important atmospheric chemical cycles (e.g., NO \(\rightarrow\) NO\(_2\)).

The reaction

\[ \text{OH} + \text{HCl} \rightarrow \text{H}_2\text{O} + \text{Cl} \] (2)

is one of the major pathways by which HCl is destroyed in plumes and in the stratosphere. The reactions

\[ \text{OH} + \text{C}_2\text{H}_6 \rightarrow \text{C}_2\text{H}_5 + \text{H}_2\text{O} \] (3)

and

\[ \text{OH} + \text{C}_3\text{H}_8 \rightarrow \text{C}_3\text{H}_7 + \text{H}_2\text{O} \] (4)

are important in hydrocarbon oxidation.

As in the case of OH \(\rightarrow\) H\(_2\) and OH \(\rightarrow\) CH\(_4\) reactions, there is a sparsity of kinetic data on Reactions (1) and (4) over the relevant combustion and plume temperatures. Therefore, \(k_1-k_4\) were measured in the temperature range of 250-1000 K.
Experimental

The experimental technique of flash photolysis resonance fluorescence described in detail in Chapter I and III were used to carry out these measurements.

CO, HCl, C₂H₆, and C₃H₈ were obtained from Matheson Gas Products. They had the following purity levels: CO, 99.99%; HCl, >99.99%; C₂H₆, >99.96%; and C₃H₈, >99.99%. CO was passed through a liquid nitrogen trap before use. HCl, C₂H₆, and C₃H₈ were subjected to degassing cycles before use.

Results and Discussion

Experimental measurements of k₁(T) for Reaction (1) are listed in Table I and plotted in Figure 1. As seen from figure 1, the curvature in the Arrhenius plot is quite dramatic. At low temperatures, the activation energy for this reaction is near zero; at higher temperatures, k₁(T) increases rapidly with temperature. [It is worth noting here that visual comparisons of the 'degree' of curvature in Arrhenius plots for several reactions can be misleading; for a reaction where the low-temperature rate constant itself depends strongly on temperature, e.g., OH + CH₄ → H₂O + CH₃, substantial high-temperature rate constant enhancement may be perceived as only moderate curvature.] As in our studies of OH reactions with H₂ and CH₄, our measurements of k₁(T) fill the gap between 500K and 1000K and verify the adequacy of the empirical forced fit expression of Baulch, et al. Our measurements of k₁(T) above 900K lie slightly above the solid line in Figure 1; it would be worthwhile to remeasure and extend k₁(T) to the 1200K temperature regime.

Rate coefficient data for Reaction (2) are listed in Table II and plotted in Figure 2. Again, the ln k₂ vs. 1/T plot is non-linear. The agreement between previous low-temperature (T < 298K) measurements and present results are excellent. However, it is clear that extrapolation of low-temperature data to higher temperatures would lead to large errors.

</table>
Rate constant data for Reactions (3) and (4) are tabulated in Table III and IV and plotted in Figures 3 and 4. Prior to these measurements, the only reliable rate constants existing for this reaction were a few measurements at and slightly above room temperature. Once again, it can be seen from Figures 3 and 4 that straight-line extrapolation of low-temperature measurements results in an underestimation of the bimolecular rate constants at higher temperatures; concave upward curvature is again evident.

The chemical kinetics experiments described above represent valuable new input to current models of hydrocarbon combustion processes. Reactions (1) is of such fundamental importance to hydrocarbon oxidation chains that accurate characterization of these \( k_1(T) \) functions is, in itself, a goal of considerable significance. Kinetic estimates for Reactions (1), (3), and (4) pervade hydrocarbon combustion modeling efforts; use of incorrect input could modify the bulk observable results of a simulated model process to an extent which implies that the assumed model structure is wrong—this may be the case, or the problem could be in the inaccuracy of the data base.

Yet one should not assume that the value of these results (and of our developed experimental technique) is limited to the numerical achievements detailed above. Typically, the complexity of the chemistry involved in a combustion and/or plume process is nearly overwhelming. In recent years it has become increasingly obvious that it is simply not possible to measure the kinetic parameters for all contributing elementary reactions in a complex process. Indeed, if such a data base did exist, computational limitations would prevent its full utilization. Increasing attention is thus being focused on the generation of 'global' kinetic equations, i.e., kinetic expressions which are approximately applicable to families of analogous chemical reactions. Such a viewpoint then argues the need for investigations...
